My experiments would seem to show that section of the dorsal roots does not affect the steadiness and indefatigability of the tonic neck and labyrinthine reflexes. If such a difference existed, it was believed that it could not be detected in any gross manner, and so the individual muscles were subjected to more careful scrutiny.

Pollock and I found that if we intoned a muscle of a decerebrate animal by evoking a tonic labyrinthine reflex, then stretched it by a gradually increasing force and, finally, gradually diminished the stretching force, the muscle failed to shorten with decrease of the pull. On the contrary, the muscle continued to lengthen; we described this as the muscle having been "pulled out." Then the muscle was first stretched, and at the height of the stretching force, a tonic labyrinthine reflex was produced. Under such a condition, the muscle shortened with decrease in the pulling force. On the other hand, if, under similar conditions, the muscle was stretched further at the time the tonic reflex was evoked, it failed to shorten with decrease in the pull and again remained "pulled out." We did not believe that these facts were due to diminished elasticity, nor did we feel that they were due to inhibition. Under the latter condition, lengthening of the muscle would be graded to the stretching force, and although this might not have been true of shortening, nevertheless, the muscle would not continue to lengthen as the stretching force decreased. It seemed most likely that the elongation of the muscle was due to a change in its physical properties which was produced by the tonic reflex. Dr. W. T. Bovie suggested to us that it was as if an elastic muscle were turned to a substance like gum, which is turned back into a substance like rubber at the first reflex activity. This property of being pulled out was present in deafferented muscles as well as in intact ones. Shortening, however, was found to be dependent on the integrity of the posterior roots.

Further confirmation of these facts was obtained by another type of experiment. If a muscle of a decerebrate animal intoned by a tonic reflex could be pulled out, we felt that it could be compressed by a force and that the indentation resulting would remain. Such proved to be the case, and the analogy between such a muscle and a gum was even more apparent. On the other hand, such an indentation produced in a normal muscle did not remain, and the muscle immediately regained its normal contour. We did not observe any difference between a normal muscle and one to which the posterior root supply had been cut. Section

of the posterior roots in a decerebrate animal had no effect on the indentation deformity produced when such a muscle had been intoned by a tonic reflex.

#### SUMMARY

1. The pattern of rigidity following decerebration depends on the level of section of the brain stem and on the influence of other reflex activities.

2. The pattern and degree of rigidity in a decerebrate animal are not changed by removal of the cerebellum.

3. Lasting patterns of rigidity in flexion occur in decerebrate animals in which the labyrinth has been destroyed, and are unchanged by removal of the cerebellum.

4. Coexisting normally distributed tone, patterns of rigidity in extension and flexion, crawling, climbing and springing are produced in animals in which a segment of the basilar artery has been isolated between two ligatures some distance apart, and in animals decerebrated at a relatively high level. Removal of the cerebellum does not affect the pattern or degree of these activities.

5. The cerebellum as a whole inhibits, in a general way, the tonic labyrinthine reflexes.

6. Removal of the cerebellum permits the regular and forceful occurrence of rhythmic reflexes in a decerebrate animal.

7. Tonic labyrinthine reflexes produce a change in the physical property of muscle which permits it to be purely mechanically stretched while other reflex adaptations occur.

8. Muscle tone may be produced by reflexes other than stretching.

# SEPARATION OF GROWTH-PROMOTING HORMONE FROM THAT INDUCING PREMATURE ESTRUS IN THE ANTERIOR PITUITARY GLAND\*

TRACY JACKSON PUTNAM

It is difficult to begin any article on the pituitary gland without a reference to the work of Harvey Cushing, who, directly through his own work and indirectly through the enthusiasm which he has inspired in his pupils, has done more than any other man to unravel that small organ's secrets. As regards the anterior lobe, it was he who first showed clearly that its subtotal removal led to a cessation of growth in young animals and an atrophy of the genitalia in mature ones.<sup>1</sup> His results were strikingly confirmed and extended by Aschner,<sup>2</sup> Blair Bell<sup>3</sup> and others, and most recently by Smith,<sup>4</sup> whose studies of the results of hypophysectomy in the rat leave little work for future investigators in this field. They have been confirmed by unpublished experiments, both in dogs and in rats, in the Surgical Research Laboratory.

## ACCELERATION OF GROWTH BY ADMINISTRATION OF ANTERIOR PITUITARY

Definite changes from administration of an excess of anterior lobe secretion were first brought about by Evans and Long, in 1921.<sup>5</sup> These investigators showed that a condition of gigantism could be produced in rats by the daily intraperitoneal injection of an unsterile aqueous (saline) emulsion of anterior pituitary substance from cattle. The most striking qualitative change was the appearance of numerous corpora lutea in the ovaries, still containing imprisoned ova. Even if injections were begun before sexual maturity in females, corpora were formed (Teel<sup>6</sup>) and ovulation failed to occur. In adults, it was inhibited.

The fertility of males was decreased.<sup>7</sup> Apparently the growth-promoting substance is destroyed by precipitating the protein with alcohol, but an estrus-inhibiting substance remains.<sup>8</sup>

At Dr. Cushing's instance, these experiments have been repeated and the results confirmed in this laboratory. By the use of an alkaline extract produced on a large scale and sterilized by filtration (a possibility suggested by Evans<sup>9</sup>), it has been possible to extend the experiment to dogs, and to bring about changes that may justifiably be termed acromegalic.<sup>10</sup> Dogs that receive injections increase in weight, and develop enlargement of the acral parts, polyphagia, asthenia, sialorrhea and spontaneous lactation. Estrus fails to appear. At autopsy, a skeletal overgrowth with hyperostoses is found, and a general splanchnomegaly. The thyroid is hyperplastic, and there are adenomas of the suprarenal gland. The most striking change is an enlargement of the entire genital tract, especially the uterus and vagina. The ovaries contain many ripe but unruptured ova, often within small cysts, but (unlike the injected rats' ovaries) no lutein tissue. The microscopic picture is much more like that seen in human acromegaly, which has recently been reviewed by Cushing and Davidoff.<sup>11</sup>

In experiments which are still in progress, it has been impossible to confirm the separation of growth-promoting and lutein-tissue-producing substance. If one is destroyed by precipitation, the other is also. Further, inhibition of estrus may be produced by various nonspecific irritating substances.

#### INDUCTION OF PREMATURE ESTRUS BY ANTERIOR PITUITARY IMPLANTATION

An entirely different series of phenomena as a result of administration of excess of anterior lobe material was demonstrated by Smith in 1926.<sup>12</sup> By the daily transplantation of fresh anterior lobe material into

immature female rats, he was able to bring about ovulation, opening of the vagina and typical estrus. An almost identical experiment was performed independently by Zondek and Aschheim<sup>13</sup> on the immature female mouse. They were able to bring on ovulation and estrus within 100 hours by a single implantation. A similar change is brought about by the injection of urine from pregnant women, and these authors suggest that it might be used as a test for pregnancy.<sup>14</sup> They draw a sharp distinction between the effect of the pituitary and that of the ovarian hormone. The former produces estrus only when the ovary is present; the latter produces estrus in the spayed animal as well. "The hypophysis is the motor of the ovary, the ovary the motor of the uterus." A detailed account of the relationship between the hypophysis and the genital tract is given by Smith and Engle.<sup>15</sup>

Transplantation of fresh and old anterior lobe material into rats has also been performed in this laboratory with results which confirm those of Smith and Zondek and Aschheim. Estrus is produced within three to five days by a single intraperitoneal implant into an immature mouse, and after a somewhat longer interval (from four to ten days) in the immature rat. Thus the mouse constitutes a more delicate test object. On the other hand, rats are—in this laboratory at least—somewhat easier to work with and more standardized, and most of the work has been done with them. Estrus is also produced more surely by a single transplant as the normal time of maturity is approached. Glands may be kept for some hours, at least, without impairment of their activity. Beef glands appear to be less effective and less well tolerated than homotransplants, but estrus has been produced in mice with them. Estrus is not produced in spayed animals, young or old, even by repeated large transplants. An important point in connection with the subject of the present paper is that daily transplants into a normal rat do not bring about increased rate of growth.

#### REPLACEMENT THERAPY IN HYPOPHYSECTOMIZED ANIMALS

So far, Smith is the only investigator who has published definite results from substitution therapy. He found that growth could be restored by the injection of an extract made according to Evans' method, but that the genital atrophy persisted. Normal development of the

genitalia as well as normal growth followed the daily homotransplantation of fresh anterior lobe, however. With Foster,<sup>16</sup> he also describes the effect of hypophysectomy on basal metabolism in rats. Metabolism remains at a normal rate following removal of the posterior lobe alone, but falls to a low level following ablation of both lobes. It is restored by administration of anterior lobe substance. The normal rise in metabolic rate following injection of glycine is prevented by removal of either the posterior lobe or of the whole gland. In the former case, administration of posterior lobe extract restores it; in the latter case, administration of both anterior and posterior lobe material is required. Neither growth nor estrus is produced by oral administration of large amounts of fresh beef gland substance.<sup>17</sup>

As these experiments gave some promise of furnishing a more satisfactory method of assaying aqueous anterior lobe extracts than that afforded by the growth of normal animals that are given injections of it, the experiments were repeated in some detail. I have performed several hundred hypophysectomies in rats, using a technic similar to Smith's. By a slight modification, it was possible to remove the anterior lobe alone. But animals prepared in this way were indistinguishable from those in which a total extirpation had been performed.

As a method of testing anterior lobe extract, the experiment proved rather disappointing. If a given extract produces growth in an animal known to be completely hypophysectomized, it may be considered active. But it is not easy to be sure that the operation is complete; and, on the other hand, those animals in which it is complete are extremely delicate, and may die after a few injections.

Determinations of oxygen-consumption were also performed. The apparatus used was a miniature Benedict apparatus immersed in a waterbath. Continuous graphic records were taken for an hour or more at a time, and fifteen minute periods free from movement were later laid out on them. Consistent values were obtained when readings were taken consecutively, but variations of from 10 to 20 per cent were not uncommon in the same rat from day to day, allowance being made of course for temperature and barometric changes. In view of this fact, only the most definite and constant changes, frequently corroborated, can be accepted as significant.

The decrease in metabolic rate following complete hypophysectomy or removal of the anterior lobe is striking, as noted by Foster and Smith.<sup>16</sup> The metabolic rate slowly declines to less than half its previous

17. Smith, P. E.: The Experimental Feeding of Fresh Anterior Lobe Pituitary Substance to the Hypophysectomized Rat, *Am. J. Physiol.* **81**:6, 1927.

value in the course of two weeks. Instead of a rise in the metabolic rate following the injection of glycine solution in the doses recommended, there is a progressive fall. In all of my experiments, the decrease in rate continued until the death of the animal from six to twelve hours later. A decrease in rate may be made out in the data given by the authors cited, but they make no mention of its fatal results.

I have not succeeded in producing any striking rise in metabolic rate in hypophysectomized rats by the administration of either filtered or unfiltered anterior lobe extract. This is another respect in which the effects of the extract differ from those of anterior lobe transplantation, as reported by Foster and Smith. It may be mentioned in passing that no definite increase in rate could be made out in normal rats at various intervals following the injection of extract and no decrease in gigantic animals when injections were omitted.

*Hyperglycemia and Glycosuria.*—These manifestations are reported by Johns, O'Mulvenny, Potts and Laughton<sup>18</sup> following injection of protein-free extracts of beef anterior lobes into dogs. I have consistently found normal blood sugar values on the various occasions on which I have determined it in dogs and rats. Glycosuria has not been demonstrated.

*The Effect of Lipoid Extracts in Spayed Animals.*—Brouha,<sup>19</sup> working in Evans' laboratory, found that acetone extracts of beef anterior lobe brought on estrus in spayed animals, as well as in normal immature females. In this he is corroborated by Fellner<sup>20</sup> who apparently believes that the estrus-producing hormone in the anterior pituitary is identical with that of the ovary, which, as is well recognized, may occur in various other tissues, as for example, fish roe and semen. Neither of these authors stated whether the ovaries of the rats thus treated exhibited the histologic changes typical of animals into which the fresh gland has been transplanted.

I have endeavored to reproduce these results without success. By extracting fresh glands with 5 or 10 volumes of acetone (Merck's chemically pure), and evaporating in a current of warm air, a yellow grease is obtained. This was implanted directly into the peritoneal cavity of some rats, in amounts of about 0.5 Gm., and 1 cc. of a saturated solution of it in olive oil was injected into others daily for a week. Glands were also extracted with boiling alcohol, ether and

acetone in succession, and the extract at each stage injected into both immature (from twenty-five to thirty days) female rats and spayed adults. None of the maneuvers produced estrus as shown by the vaginal smear, or a change in the internal genitalia at autopsy.

*The Effect of Implantation of the Residue Left After Aqueous and Acetone Extraction.*—As a control experiment to the implantation of the semisolid grease obtained by acetone extraction, some of the tobacco-dustlike gland residue was inserted into the peritoneal cavity of an immature female rat. Much to my surprise, this control was the only one which showed premature opening of the vagina and cornified cells in the smear. This occurred on the fourth day after implantation. At autopsy, the ovaries were found to be enlarged and to contain hemorrhagic spots, and the uterus was thickened and distended, exactly as after gland-transplantation. The experiment was repeated on three other immature rats, with the production of estrus on the fourth and fifth days. In one mouse weighing 8 Gm., estrus was produced the day following the injection, in another weighing 7 Gm. on the fourth day.

Since the aqueous extract containing the growth-promoting principle does not produce premature estrus, the next obvious step was to see whether the residue left from its preparation showed any activity after drying with acetone. The same results were obtained. The residue remains active after extraction with alcohol and ether also.

#### PREPARATION OF MATERIAL

The preparation and properties of the material now in use is as follows:

Fresh or frozen pituitary glands are received from the slaughter-house, and the anterior lobes are dissected out and ground fine in a meat-chopper. They are extracted with 4 volumes of weak alkali (0.8 per cent  $\text{Na}_2\text{CO}_3$  is being used at present), and the filtrate is put through the steps previously described to make the growth-producing extract.

The residue is washed with about 10 more volumes of dilute alkali, being thoroughly stirred meanwhile; then with several volumes of tap water. It is drained and pressed between filter-papers and extracted with about 4 volumes of 95 per cent alcohol. The alcohol may be heated to boiling. The residue is partially dried, and ether is poured over it on a filter-paper. Finally, it is thoroughly soaked in several volumes of acetone, dried on filter paper and pulverized in a mortar. It may be sterilized by soaking in alcohol, but for use with rats and mice this is not necessary.

As a test-object, female rats or mice are taken a few days after weaning. Younger animals are more difficult to bring into estrus, and also survive the rather heroic treatment less well.

The animal is etherized, the abdomen smeared with antiseptic ointment and a median incision about 1 cm. long is carried through into the peritoneal cavity. (Asepsis is unnecessary with small rodents.) Through this, from 0.1 to 0.2 Gm. of the dried residue is introduced—about as much as is taken up by a pair of

forceps. The wound is closed in two layers with one or two stitches in each, and the animal released.

The vagina is examined daily. Premature opening and a cornified smear are reliable signs of the activity of the material implanted. Sometimes the cornified stage is missed, however, and in any case the most definite evidence of estrus is furnished by the typical appearance of the ovaries and uterus at autopsy (fig. 1) as described by Smith. Sometimes, in the case of rats less than 30 days old, a second implant is required from three to four days after the first, to bring about estrus. About 10 per cent of the animals die of intestinal obstruction.

As control experiments, the alkaline, acid, alcoholic and acetone extracts have been implanted or injected, in single doses and repeatedly, without producing estrus. On the ground that the effect might be due

Uteri and ovaries of littermate rats, 32 days old. The animal whose genital tract is shown at the left had received an intraperitoneal implantation of anterior pituitary residue (seen in the inflammatory mass below) five days previously. The control animal (genital tract shown at right) had received a drop of oleic acid intraperitoneally at the same time.

to simple mechanical or chemical irritation, small quantities of sand, sawdust and oleic acid have been implanted, also with negative results.

I have failed to produce estrus in spayed animals by use of the acetone residue.

#### IS THERE MORE THAN ONE HORMONE IN THE ANTERIOR PITUITARY?

Certainly parenteral administration of anterior lobe substance brings about several different effects which are difficult to reduce to a common denominator—for example, the lactation in a virgin dog, the formation of osteophytes and the appearance of adenomas in the suprarenal

following repeated injections of filtered aqueous extract. It is tempting to believe that each of these actions may be due to a separate chemical substance, but at present no proof is at hand.

It is more profitable to approach the question from the standpoint of the physical and chemical properties of the material employed. There seems to be evidence that injection of an (alkaline) aqueous extract of beef anterior lobe brings about results which are different from those following implantation of the insoluble residue. The former causes chiefly growth of mesodermal tissues, and the formation of corpora lutea, rather than ovulation. The latter stimulates the growth of ova and produces premature estrus. It seems justifiable to draw the tentative conclusion that these two general effects at least are due to two different chemical substances.

Such a conclusion cannot yet be considered final. At least one hormone—the estrus-producing principle of the ovary—is recognized to exist in a water-soluble as well as a lipoid-soluble form. It is conceivable that extraction with even large amounts of fluid fails to remove all of the hormone (supposing for the moment there is only one) and that the residue contains some of it in an insoluble form. Possibly the difference in effect of the two materials is due to a difference in amount or rate of absorption of the same substance. The aqueous extract may contain a much greater amount of it, and the formation of corpora which prevent ovulation may be a later stage of the stimulation of growth of ova. One should then have to suppose that the estrus-producing substance demonstrated in the urine of pregnant women by Zondek and Aschheim is still a third chemical individual.

So far, however, variations of dosage of either the aqueous extract or the residue respectively have failed to elicit the response characteristic of the other substance. Moreover, even if one substance may be converted into another—as for example, mild mercuric chloride into corrosive sublimate—it is still well to draw a distinction between them if they exhibit different biologic properties.

#### CONCLUSIONS

1. The residue left after extraction of beef anterior pituitary glands with mild alkalis, acids, alcohol and acetone is capable of producing premature estrus when implanted intraperitoneally in young rats or mice.

2. This effect is apparently identical with that produced by homo-transplants of rat anterior lobes into immature females, as observed by Smith and others.

3. The effect appears to be distinct from that brought about by (alkaline) aqueous extracts from the same glands.

4. It seems probable, therefore, that there are at least two chemically distinct hormones in the anterior pituitary, which may be separated in the manner indicated.

NOTE.—A few days after this paper was sent to the printer the article by Evans and Simpson (Antagonism of Growth and Sex Hormones of the Anterior Hypophysis, *J. A. M. A.* **91**:1338 [Nov. 3] 1928) appeared, which not only anticipates but amplifies the present paper.

Still more recently, Mr. Harold Teel called my attention to an article by Spaul (Experiments on the Localization of the Substances in Pituitary Extracts Responsible for Metamorphic and Pigmentary Changes in Amphibia, *Brit. J. Exper. Biol.* **2**:427, 1925). I have found that an acid extract made according to his procedure produces estrus in immature rats also. Many discrepancies are thus explained.

Dr. Edward B. Benedict and Mr. Harold Teel have allowed me to use some of their observations, which are published here for the first time.

# STUDIES IN ACROMEGALY

## VIII. EXPERIMENTAL CANINE ACROMEGALY PRODUCED BY INJECTION OF ANTERIOR LOBE PITUITARY EXTRACT \*

TRACY J. PUTNAM,

EDWARD B. BENEDICT

AND

HAROLD M. TEEL

The possibility that the peculiar and distinctive disorders, acromegaly and acromegalic gigantism, were due to overactivity of the anterior lobe of the pituitary body has been suspected for many years. Although other data were not lacking to confirm the suggestion, it may be said that the possibility was first transformed into a probability by the production of gigantism in rats by injections of an emulsion of the anterior lobes of beef hypophyses by Evans and Long.<sup>1</sup> Their prodigious animals could not actually be considered acromegalic, however. They underwent a general proportionate enlargement, but aside from a peculiar change in the ovaries they showed no qualitative structural alteration. The absence of the specific enlargement of the "acral parts," which gives the disease its name, might be attributed to the fact that in the rat the bony epiphyses never unite. It obviously became desirable to extend the experiment to larger animals in which the epiphyses become closed.

This became feasible only when large quantities of a stable, sterile anterior lobe extract were available. The preparation of such a material was described in an earlier article.<sup>2</sup> Several modifications in the method of extraction have been made since the experiment was begun,<sup>3</sup> but they need not concern us here. Dogs were chosen as suitable experimental animals.<sup>4</sup>

### REPORT OF EXPERIMENT

Two pedigreed thoroughbred English bulldogs, female littermates, aged 4 weeks, were received on March 1, 1927. They were observed in the laboratory for three weeks, and were found to grow and behave as normal puppies should.

arity with methods of preparing and handling the fluid was gained, disturbances of this sort occurred less and less frequently.

By May 1, it became apparent that the dog which received the injections was growing faster than the control. From that time on, there was an increasing

Fig. 7.—March 21: Enlargement of the teats of the experimental animal, from which colostrum could be squeezed. The legs and paws are noticeably enlarged

Fig. 8.—May 30: Ventral view of the experimental animal. The laxity of the skin and the development of the udders is even more pronounced.

Fig. 9.—May 30: Experimental animal, showing plantigrade gait, sunken head and protruding tongue.

difference between their respective weights (fig. 1). The dose was increased on May 8 to 20 cc., which again caused vomiting for a few days. A sort of tolerance seemed to establish itself later, and except for the slightly increased rate of growth, there was little difference between the dogs in appearance or behavior.

On June 14, measurements of the two animals were made, as shown in table 1.

On July 6, the fasting blood sugar was found to be 89 mg. for the control and 80 mg. for the animal given injections. Single specimens of urine contained no sugar.

From July 3 to 25, both dogs suffered from an epidemic infection of the upper respiratory tract, and both remained practically stationary in weight throughout the month. On July 27, the dose was increased from 20 to 30 cc. There was still no immediate gain in weight, perhaps because of the excessively warm weather which prevailed.

\* Calcium determinations were made by Collip's method, phosphorus determinations by Fiske and Subbarrow's method.

Qualitative structural differences began to be noticed about this time. The lower jaw of the animal which was given the injections was perceptibly longer than that of the control. The tongue was larger, even in proportion to the generally increased size. The experimental animal stood higher than its control. X-ray pictures taken on July 20 showed that its skull was larger, and that its long bones were longer and heavier than those of the control animal. There appeared to be no particular change in the epiphyses.

In August, 1927, a definite difference in behavior appeared. The animal receiving the injections became weak and languid, and could scarcely be persuaded to leave its favorite corner. Its muscular movements were so poorly controlled that it would often fall in trying to jump from a chair. This general weakness steadily progressed. Meanwhile, rapid growth also continued. The appetite became noticeably greater.

By October, 1927, this sluggishness was still more striking. In walking, the forepaw as far back as the hock rested on the ground. The animal was plantigrade rather than digitigrade. The claws became long and curved, perhaps from lack of wear. Owing to the laxity of musculature, the spine sank between the scapulas, and the experimental animal, though much heavier, stood less high than

its control. A prolapse of the vagina became noticeable, but there was no discharge from it. A stubborn diarrhea developed. The abdomen became large and pendulous.

The sudden loss of weight in both animals, recorded on November 16, was never satisfactorily accounted for.

On December 4, chemical analyses of the blood (fasting) gave results as shown in table 2, expressed in milligrams per hundred cubic centimeters.

The differences were not sufficiently striking to encourage further determinations at this time.

On December 8, measurements of the animals were again made as shown in table 3.

About December 14, both animals again contracted an epidemic infection of the respiratory and gastro-intestinal tracts lasting for several weeks and causing a loss of weight of about 5 Kg. in the animal receiving the injections (fig. 2).

When both animals had fully recovered, the daily dose was increased to 50 cc. (Jan. 30, 1928). The sudden increase in weight which ensued is doubtless to be attributed largely to the improvement in the animal's general condition.

On March 7, 1928, it was found possible to squeeze colostrum (verified microscopically) from the udders of the experimental animal which had reached an abnormally large size (figs. 7 and 8). At this time, the teats of the control animal were barely visible. The udders of the experimental animal ceased to secrete toward the end of May, but they continued to be larger than those of the control, in spite of the fact that the latter developed the normal pubertal hypertrophy.

The control animal went into heat in April. The animal that was given injections never went into heat, although the prolapse of the vagina became enormous, a cuff about 5 by 6 cm. which occasionally dragged on the ground (figs. 6 and 8).

From April 18 to May 23, neither animal gained appreciably in weight, although the qualitative changes in the experimental animal constantly grew more pronounced. Accordingly, the daily dose was increased to 75 cc. of extract on the latter date. At about this time, a small fibroma appeared in the epigastrium.

June 14 was an unusually warm day. The experimental animal appeared as usual in the morning, and was let out on the roof with the other dogs. Toward the end of the afternoon, it was found lying dead in the sunshine. The other animals did not appear adversely affected by the heat.

*Autopsy*—An autopsy was performed immediately. The cadaver weighed 44 Kg. The body was still warm; indeed, there seemed to be a postmortem hyperthermia. The epidermis peeled off in large patches, as if sunburned.

The control animal was killed by etherization on the following day. The cadaver weighed 23.3 Kg. An equally complete autopsy was performed, which revealed no abnormalities. The respective observations in the two animals are

Fig. 10.—Tongues and tonsils: experimental animal, right; control, left. Note the spreading apart of the papillae at the base in the larger specimen;  $\times \frac{1}{2}$ .

described together. A comparison of the weights of the various organs and bones is given in table 1.

Whereas the control animal had a normal panniculus, in the dog which was given the injections there was an almost complete absence of subcutaneous and omental fat; only a few brownish shreds appeared here and there. The musculature was disproportionately small and soft, and the voluntary muscles were a dull grayish red, contrasting with the bright red, heavy muscles of the control animal. There was a great engorgement of vessels everywhere in the experimental dog.

In neither animal was there free fluid or adhesions in the abdomen or pleura. The tongue of the experimental animal was greatly enlarged (fig. 10).

The thyroid of the treated animal appeared much enlarged and more deeply colored than that of the control; that of the experimental animal weighed 10 Gm and that of the control, 1.7 Gm. No thymus tissue could be identified in gross section in either animal.

The weight of the heart of the experimental animal was double that of the other (fig. 11), and its myocardium was soft and grayish, like the voluntary musculature. It weighed 380 Gm.; that of the control animal, 170 Gm. The lungs were engorged, purple and soft, but not crepitant; they sank in water. Pink foam could be squeezed from the bronchii and from the cut surface. In the control animal, the lungs were pink, dry and crepitant. There were no areas of consolidation in either animal. In the experimental animal, the lungs weighed 545 Gm; in the control animal, 160 Gm.

Fig. 11—Hearts; the enlargement is most noticeable in the ventricle of the animal which received the injections (left);  $\times \frac{1}{2}$ .

The liver of the larger animal was enormous (fig 12). It contained an excess of blood, but when this was allowed to escape from a portion of it, the color was seen to be a rather lighter brown than that in the control. The architecture was normally prominent. It weighed 2,200 Gm.; that of the control animal, 645 Gm. The spleen was similar in size and appearance in the two animals. Its weight in the larger animal was 43 Gm.; in the control animal, 39 Gm. The pancreas (fig. 13) was more reddish and translucent in the experimental dog and weighed 128 Gm; in the control animal, it weighed 48 Gm.

The peritoneum was smooth, pale and glistening everywhere in both animals. There was no evidence of damage from the repeated injections. The omentum was free; that in the animal which was given injections contained little fat but a rather large amount of brownish pigment.

Fig. 12.—Livers (seen from above): experimental animal, right; control, left;  $\times \frac{1}{3}$ .

Fig. 13.—Pancreas; the darker color of the specimen from the experimental animal (right) is due partly to congestion and partly to postmortem change;  $\times \frac{1}{2}$ .

Fig. 14.—Stomachs; note the trabeculated appearance of the specimen from the experimental animal (right);  $\times \frac{1}{2}$ .

Fig. 15.—Kidneys; slight adhesions of the capsule and engorgement of the surface vessels are seen in the organ from the experimental animal (right);  $\times \frac{1}{2}$ .

The stomach (fig. 14) of the experimental animal was capacious, relaxed, and pendulous, but the walls and lining appeared normal. Unopened, it measured 27 by 19.5 cm.; in the control animal, 13 by 9 cm.

The intestines seemed normal in structure and contents in both animals. They were not measured. No parasites were found.

The kidneys (fig. 15) were much enlarged and bluish in the animal given injections. The capsule was adherent. Grossly, both the cortex and the medulla of this

Fig. 16.—Vaginae, uteri and left ovaries; the vaginae have been laid open by an incision along the anterior wall. Note the rugosity and thickness of the specimen from the treated animal (right); about  $\times \frac{1}{3}$ .

animal were increased as compared with those of the control animal. The weight of both kidneys in the treated animal was 304 Gm.; in the control animal, 125 Gm. The ureters were normal, but the bladder was unduly large in the treated animal.

The suprarenal glands of the injected animal, which did not appear disproportionately enlarged or altered, weighed 3.4 Gm.; those in the control animal, 2.3 Gm.

The ovaries were large in the treated animal. No corpora could be made out in gross section in either dog. The weight of the right ovary in the experimental animal was 32 Gm.; in the control animal, 8 Gm. The uterus and vagina (fig. 16) showed the most striking changes in the entire body. The uterine horns were long, 13 cm. in the injected animal as compared with 5 cm. in the control, and stretched well up into the hypochondrium. They were approximately twice the diameter of those of the control. The vagina was greatly elongated, and the tissue thick and deeply furrowed.

Fig. 17.—Skulls; note the asymmetry and wide separation of the teeth, the spread of the zygoma and the ruggedness of the base in the larger animal (right);  $\times \frac{1}{2}$ .

The brain appeared normal in both animals, that of the experimental animal weighing 112 Gm., and that of the control, 95 Gm. The hypophysis, which also appeared normal in gross section, weighed 1.3 Gm. in both animals.

The skeletons of both animals were prepared. The skull of the treated animal was larger (figs. 17 and 18), especially the lower jaw (fig. 19). The teeth were larger and more widely spaced. The upper incisors and canines were symmetrical (fig. 17). The walls of the frontal sinus were thick, although the cavity itself was no larger than that of the control animal. The site of origin of the temporal muscle was abnormally roughened, and the skull as a whole presented an unusually rugged appearance.

Fig. 18.—Skulls, opened (dorsal view); a trephine opening has been made into the thick-walled, right frontal sinus of the specimen from the experimental animal (right). Note the increase in the diploe and the size of the foramina;  $\times \frac{1}{2}$ .

Fig. 19.—Right mandibles (inner aspect); the specimen from the treated animal (above) is larger and rougher, and has enlarged processes and widely spaced teeth;  $\times \frac{1}{2}$ .

The long bones were obviously enlarged, and their prominences bore osteophytes, seen most clearly in the tibia (figs. 20 and 21). The patella also showed osteophytic changes (fig. 22). The digits did not show the spurs characteristic of acromegaly in man. Separate flakes of bone lay in the anterior ligament of the spine (fig. 23).

*Microscopic Examination.*—Muscles: No definite difference between the two animals was distinguished in the voluntary musculature taken from various parts of the body.

Fig. 20.—Right tibiae and fibulae; note the osteophytes on the head of the tibia of the experimental animal (right);  $\times \frac{1}{2}$ .

*Tongue:* A block was taken from a homologous situation in each animal—the base of the tongue, in the region of the circumvallate papillae. The piece from the injected animal was larger. Much of the cornified epithelium had been rubbed off, but where it remained, it was far thicker than that in the control animal. More striking was the increase in fibrous tissue which separated and surrounded the bundles of muscles. The muscular tissue itself appeared similar in the two animals.

Fig. 21.—Right femora (posterior aspect); note the enlargement and ruggedness of the specimen from the treated animal (right);  $\times \frac{1}{2}$ .

Fig. 22.—Right patellae; that of the experimental animal (right) is enlarged and bears many osteophytes; natural size.

Fig. 23.—Last two lumbar vertebrae and sacra; note the hypertrophy of the transverse processes and the loose osteophytes overlying the intervertebral disks in the specimen from the experimental animal (right);  $\times \frac{1}{2}$ .

Fig. 24.—Pelves: experimental animal, right; control, left; about  $\times \frac{1}{2}$ .

**Thyroid:** Sections from the experimental animal showed an abnormally dense and cellular structure (fig. 25). The acini were small, and many of them stellate or flattened. Some of the acinar walls appeared to be lined with two layers of low columnar epithelium, and similar cells filled the lumen of many. There was a striking paucity of colloid. In some sections, none was to be found. Occasionally its place was taken by an amorphous precipitate.

Sections of thyroid, not only from the control but from other dogs killed in the laboratory, showed acini of varying size, but practically none without hyaline masses of colloid, and lined with low cuboidal or flat epithelium

Fig. 25.—Thyroids: experimental animal, right; control, left. Note the high epithelium, collapsed alveoli and absence of colloid in the specimen from the experimental animal. Methylene blue and cosin;  $\times 80$ .

**Heart:** No difference in size of fibers, straining or amount of connective tissue was made out.

**Lungs:** There was a congestive edema of the lungs of the treated animal (fig. 26). Most of the alveoli were filled with an amorphous protein precipitate containing a few red cells. A few were widely distended with air. There was no bronchitis, and no purulent or fibrinous inflammation. The capillaries were congested. By comparison, the normal lung appeared particularly empty and delicate. There was no striking difference in the general size of the alveoli between the two lungs.

**Liver:** The striking observation made on the animal which had been given the injections was the passive congestion, with central necrosis and the disappearance of liver cells (fig. 27). Almost all the cords of the liver were thin; often they were vacuolated and stained poorly. The sinuses were filled with blood and amorphous debris. In some places, the blood clot had fused into a hyaline mass. There was little abnormal pigmentation and no fibrosis. The control furnished an imperfect comparison, because it showed a slight fatty infiltration, not uncommonly seen in animals in captivity.

Fig. 26.—Lungs: experimental animal, right; control, left. Passive congestion and edema are present in the specimen from the treated animal. Methylene blue and eosin;  $\times 80$ .

**Pancreas:** The specimen from the animal which had been given the injections had undergone some postmortem change. The nuclei did not stain sharply. The cells were similar in size and general appearance to those in the control. There was perhaps a little interstitial fibrosis. Islet tissue was relatively not increased in amount; if anything, it was decreased. There was no fibrosis or change in the aspect of the cells.

**Spleen:** Aside from a moderate degree of fibrosis, the spleen of the experimental animal did not differ from that of the control animal.

Kidney: The specimen from the animal which had been given the injections showed the universal vascular congestion (fig. 28); however, the blood vessels in the specimen from the control animal were well filled also. There was a definite disparity in size between the secretory units. It was difficult to find a glomerulus in the injected animal which did not extend beyond the limits of an immersion

Fig. 27.—Liver: experimental animal, right; control, left. Passive congestion, central necrosis and enlargement of the lobules are seen in the specimen from the treated animal; slight fatty infiltration is present in the specimen from the control. Methylene blue and eosin;  $\times 80$ .

field, whereas none were to be seen in the control which reached these limits. The count of glomeruli in low power fields, close under the capsule, varied from 4 to 11 in the treated animal, and from 8 to 19 in the control animal. Corresponding portions of the tubules appeared larger in the experimental animal, but this was hard to estimate quantitatively.

The individual cells in corresponding situations were similar in the two specimens. The cells lining the tubules appeared somewhat larger in the experimental animal, but this might have been due to a slight cloudy swelling. Those in the capillary tuft appeared a little smaller, and less densely packed; yet the number per

Fig. 28.—Kidneys: experimental animal, right; control, left. Note the increase in interstitial tissue and the relative enlargement of tubules and glomeruli in the treated animal. The fields were chosen to include as many glomeruli as possible; yet parts of only four appear in the specimen from the experimental animal. Methylene blue and eosin;  $\times 80$ .

glomerulus seemed somewhat increased. There was no leukocytic or fibrous infiltration in either specimen. In the injected animal, an occasional capsule contained precipitated albumin and blood.

Suprarenal Gland: Of the two sections passing through the greatest width of the suprarenal gland, that taken from the animal which was given the injections was obviously the larger (fig. 29). It measured 28 by 6 mm., as compared with 24 by 4 mm. in the control animal. The increase in size appeared to be due

Fig. 29.—Suprarenal glands: experimental animal, right; control, left. Medulla, below; cortex above. Note the adenoma in the lower part of the control specimen. The structural units are spread apart, but the cells do not appear to have increased in size. Methylene blue and eosin;  $\times 80$ .

chiefly to an enlargement of the cortex, in which all three zones shared. The zona glomerulosa was prominent, and took a deep stain. The cells contained fewer lipoid vacuoles than those of the control animal. The narrow cell cords of the zona fasciculata were somewhat spread apart by spaces containing coagulated

protein. There were numerous small adenomas averaging about seven to a section, and measuring up to 1 mm. in diameter. They were composed of knots of cells resembling those of the glomerular zone, arranged about a rather heavy connective tissue stroma. They were situated in the depths of the middle zone. The zona reticularis was expanded; it could be clearly seen that the increase in area was chiefly due to an increase in the size of the blood vessels and the amount of stroma. Throughout the cortex, it appeared that the parenchymal cells were smaller, contained less lipoid and, consequently were darker-staining than those of the control animal. The nuclei were oval and dark. The densely packed, even columns of light colored, flattened cells, typical of the normal suprarenal gland were nowhere to be found.

The suprarenal medulla was rather vaguely distinguishable from the adjacent reticular tissue; it appeared to be decreased in area as compared with that of the control animal. The cells were spread apart and separated from their stroma, giving the tissue a loose and open appearance. In many of the cells, the outline

Fig. 30.—Cross-section of the normal uterus of the control animal. Comparison should be made with figure 31. Methylene blue and eosin;  $\times 10$ .

of the protoplasm was indefinite, as if partially disintegrated; indeed, often only the nuclei of cells were seen. They contrasted sharply with the closely packed, uniform cells of the control animal.

**Uterus:** The whole section (figs. 30 and 31) was manifestly larger in the experimental animal; the greatest diameter was 11 mm., as compared with 6.5 mm. in the control animal. The epithelium lining the large stellate lumen and the glands immediately subjacent was columnar rather than cuboidal. More outlying glands were much distended, forming tortuous lacunae and cysts as large as 2 mm. in diameter, lined with low epithelium. These were represented in the control animal by solid cords of cuboidal cells, without lumen. The amount of interstitial fibrous tissue was increased, but it appeared less cellular than in the normal control animal.

The muscular coat was not notably increased in thickness, although of course its circumference was greater. There was a paucity of fat in the parametrial tissues; the fat that was present was of the small cell "fetal" type.

There was no striking difference between the respective fallopian tubes of the two animals

Breast: With the naked eye, the epithelium of the nipple in the experimental animal was seen to be thicker than that in the control animal (fig. 32). This thickening appeared also in the walls of the hair follicles. The tubules were large in the animal receiving the injections; the lining epithelium was tall and also thrown into folds. In the control animal, the glandular tissue was arranged in compact masses of collapsed alveoli, lined with small, inactive cells—the normal arrangement in the virgin female.

Ovary (figs. 34 and 35): The size of a section through its greatest diameter was strikingly larger in the experimental animal, which showed 14 mm. as compared with 8.5 mm in the control animal (fig 34 and 35). Two large corpora lutea (3.5 mm), composed of plump, fat filled lutein cells, occupied most of the

Fig. 31—Cross-section of the uterus of the experimental animal. Note the increase in diameter compared with that of the control animal (fig. 30), and especially the distention of the glands and lumen. Methylene blue and eosin;  $\times 10$

area of the normal section. The size of the section in the experimental animal was largely due to a great excess of stroma. In addition, most of the follicles seen were enlarged but unruptured. Many of them contained ova of normal aspect. Some of the follicles were filled with cells having irregular or elongated nonfibrous protoplasm and round or oval chromatin-containing nuclei, which did not in the least resemble normal lutein cells. In these, the follicular lining was indefinite; one received the impression that the whole structure was becoming organized and obliterated. Other small cysts were seen which contained an amorphous precipitate and a few desquamated cells.

In addition to these unfamiliar structures, a few normal unripe follicles were seen. It was impossible to say whether the total number of these was increased or decreased.

The fallopian tube was enlarged and thickened in the animal which had been given the injections. Its lining appeared normal.

**Hypophysis:** There appeared to be an increase in the amount of fibrous tissue in the anterior lobe in the experimental animal. The parenchyma appeared normal in both animals, and there seemed to be a normal relationship between the different types of cells. A few hyaline cysts were visible in both specimens.

Little was seen of the intermediate lobe in the animal receiving the injections, as the specimen was separated in handling. It appeared normal, however.

Fig. 32.—Mammary glands: experimental animal, right; control, left. Note the high, rugose epithelium of the gland of the experimental animal, resembling that of a lactating gland. Methylene blue and eosin;  $\times 80$ .

In the posterior lobes, little difference appeared in the specimens of the two animals. The vascularity was about equal. In the injected animal, there was, perhaps, a larger number of hyaline masses, apparently degenerated cells, and there were more hyalinized fibers in bundles and whorls. One hyaline cyst was seen in the larger animal.

**Summary.**—The animal which received an aqueous extract of the anterior lobe of the hypophysis showed, during life, an enlargement of the "acral parts," a lack of estrus, cutaneous disturbances, drowsiness, asthenia, gain in weight, polyphagia and polydipsia, fibroma of the skin, sialorrhea and persistent lactation. The animal

died, apparently of myocardial failure and edema of the lungs, after fourteen months of daily injections.

At autopsy, an elongation of the long bones and mandible, thickening of the skull and the formation of osteophytes were found. There was a pronounced splanchnomegaly, most striking in the thyroid, uterus and vagina. However, the

Fig. 33.—Skin and subcutaneous tissue: experimental animal, right; control, left. Note the thickening of the cutis, especially the horny layer in the specimen from the animal given injections. Methylene blue and eosin;  $\times 0$ .

heart, lungs, liver, pancreas, kidneys, suprarenal glands and ovaries were also enlarged to a disproportionate extent. The factor of long-standing congestion must be taken into account in some of these organs—particularly the lungs, which were edematous—but, obviously, cannot explain the full extent of the changes. Of the

important organs, the brain, hypophysis and spleen alone were of a size comparable to those of the control animal.

Microscopically, a varying degree of increase of connective tissue was observed in all organs. The ovaries contained many ripe unruptured follicles, still containing ova. The thyroid alveoli contained practically no colloid, and were collapsed and irregular in shape. The epithelium was high and irregular. The whole picture suggested that of toxic goiter in man. There were microscopic cortical adenomas in the suprarenal glands. The renal tufts were definitely larger than those seen in the control animal.

Fig. 34—Greatest cross-section of the ovary of the control animal, surrounded by the fimbriated extremity of the tube. Two corpora lutea occupy most of the bulk of the ovary, in sharp contrast to that shown in figure 35. Methylene blue and eosin;  $\times 10$ .

#### COMMENT

One need but glance at the list of symptoms given in any clinical treatise on acromegaly (for example that of Davidoff,<sup>5</sup> p. 469) to see how completely the manifestations of this experimentally produced condition fit into it. Not is the parallel between the observations at autopsy in this case and in cases in man less close. To refer again to a previous

5. Davidoff, L.: Studies in Acromegaly. II. The Anamnesis and Symptomatology in One Hundred Cases, *Endocrinology* 10:461, 1926.

paper in this series, Cushing and Davidoff<sup>6</sup> laid particular emphasis on the splanchnomegaly which has appeared in greater or less degree in all the cases which they studied. The presence of adenomas of the supra-renal gland and, in one instance studied, of an enlargement of the ovary with failure of ripe follicles to rupture is also recorded in their paper.

Two points in the comparison between the structural changes found in the dog which was given the injections and those seen in spontaneous acromegaly deserve further consideration. In the first place, the

Fig. 35—Greatest cross-section of the ovary of the experimental animal, showing an increase in interstitial tissue, and the imprisonment of ova within unruptured follicles, some of which are in process of obliteration. Comparison should be made with figure 34. Methylene blue and eosin;  $\times 10$ .

definitely hyperplastic changes seen in the thyroid gland were more striking than those usually seen at autopsy in human beings. Indeed, acromegalic thyroid glands at autopsy often show the structure of a

6. Cushing, H., and Davidoff, L.: *Studies in Acromegaly: V. The Pathological Findings in Four Autopsied Cases of Acromegaly with a Discussion of Their Significance*, Monographs of the Rockefeller Institute, New York, 1927, no. 22, p. 1.

"colloid" adenoma, according to Cushing and Davidoff.<sup>7</sup> It is probable that the latter condition is a later, relatively inactive stage of acromegaly, for instances are on record in which the thyroid has been removed from acromegalic patients on the ground that it was hyperplastic.

In the second place, the incredible enlargement of the uterus and vagina appears to be without parallel in autopsy material obtained from man. Perhaps it was not specifically looked for. That this enlargement is no accidental observation in experimental canine hyperpituitarism is shown by the fact that it occurred in three other female dogs experimented on, though not yet reported, even after injections for as short a period as two months. No comparable overgrowth is seen or reported in female rats which are given injections. On the other hand, characteristic "mulberry ovaries," containing corpora lutea and ova, are produced in the rat by filtered extract of the anterior lobe, but not in the dog. The canine ovaries rather resemble those in the case reported by Cushing and Davidoff in a human being.

The hypertrophy of the genitalia of the dog in the case here reported suggests that the fluid used contains the second hormone of the anterior lobe, recently separated by Evans and Simpson,<sup>8</sup> which produces premature sexual maturity in the rat.

In general, however, the condition as it occurs spontaneously in human beings appears to correspond closely with that produced in the dog experimentally.

#### SUMMARY AND CONCLUSIONS

1. A dog which received daily for fourteen months a sterile aqueous extract from the anterior lobe of beef hypophyses grew to almost twice the weight of its littermate control. It developed among other conditions, enlargement of the acral parts, polyphagia, asthenia, sialorrhea and spontaneous lactation.

2. The animal succumbed to myocardial failure and edema of the lungs. A skeletal overgrowth with hyperostosis was present. There was a generalized splanchnomegaly, affecting the thyroid and genital tract most strikingly. The thyroid was hyperplastic, there were adenomas of the suprarenal gland and the ovaries contained ripe but unruptured follicles.

3. The condition produced appears to merit the designation of experimental acromegaly.

# TREATMENT OF HYDROCEPHALUS

## HISTORICAL REVIEW AND DESCRIPTION OF A NEW METHOD\*

LEO M. DAVIDOFF

Many fundamental questions concerning the cerebrospinal fluid, as, for example, whether it is wholly or only partially produced by filtration through the choroid plexus, remain unsolved. But the discoveries of modern workers, from Magendie through Cushing and his pupils, concerning the nature, origin, outlet and functions of the "third circulation," leave one free to enter on a discussion of the therapy in diseases affecting it, without first having to consider these other aspects.

In many papers on the treatment of hydrocephalus, the confidence of the authors in their own methods leads them to pass briefly over the efforts of others in the same direction. The present writer, from the beginning, must confess to a feeling of trepidation at offering still another method, and will at least review in some detail the multitudinous schemes presented—especially during the past forty years—for the cure of this distressing condition. Each one has its own merits, even though all together fail to accomplish their aim except in a small percentage of cases.

### TREATMENT BEFORE THE DAYS OF ANTISEPTICS

Hydrocephalus was known to the ancients, but its treatment in their hands was not founded on sound physiologic principles. Although Hippocrates is repeatedly credited with having punctured the dilated ventricles through the open fontanelle or after trephining the skull, this fact could not be confirmed by referring to his writings.\* Whytt<sup>93</sup> quoted him as proposing treatment by making a perforation in the upper part of the cranium, but not by probing the brain itself. In Littré's "Translation," volume 10, only a brief passage exists on the "dropsies coming from the head," in which such treatment is recommended as making three scars on the neck, warming the frontal region and cooling the occipital, purgation, etc.

Children born with large heads containing an excess of fluid were recognized throughout the ages as anomalous beings. Vesalius<sup>94</sup> gave an account of a child of two years whose head was greatly enlarged and in the ventricles of whose brain were found nine pounds of water. Hieronymus Mercurialis,<sup>95</sup> who flourished in the beginning of the six-

---

\* From the Laboratory of Neuropathology of the New York State Psychiatric Institute.

\* Dr. Fielding H. Garrison was kind enough to lend me the benefit of his wide experience in this search.

teenth century, mentioned the collection of water in the ventricles of the brain as a thing that might possibly occur. Boerhaave<sup>5</sup> also spoke of it, calling it a species of the *Hydrocephalus*. It was not until 1768, however, that Robert Whytt made his "Observations on the Dropsy in the Brain" occurring in children after the sutures had closed, and thus unaccompanied by any appreciable enlargement of the head. Concerning the treatment of hydrocephalus, this astute observer expressed a truth that remains practically unchallenged today, when he wrote that in the latter stages of the disease when "so much water is accumulated as, by its pressure on the sides of the ventricles, to disturb the action of the brain, we have little to hope from medicine."

For the most part, treatment of hydrocephalus, and of meningitis—the latter was usually looked on by the older writers as the early stages of hydrocephalus, as, indeed, it often is—followed the therapeutic fashions of the times. Thus, as late as 1843, Professor Bennett<sup>3</sup> of London, in a prize essay on ". . . Water in the Head" wrote that "in the strictly acute inflammatory forms there can be no doubt that blood-letting is our sheet anchor." He condemned blood-letting by venesection in the chronic forms and recommended cupping and leeching in the vicinity of the mastoid. Purges and diuretics were used on the strength of the argument that these measures were efficacious in the treatment of dropsies in other cavities of the body, and might, therefore, be useful here. More special types of therapy employed in pre-Listerian times will be discussed in their appropriate places.

#### TREATMENT WITH DRUGS

Our heritage from the distant past relating to the treatment of hydrocephalus by means of drugs may be safely forgotten. It had no pretensions to anything beyond the aims of the honest practitioner who confided to his assistant that in whatever ailment he was called on to treat . . . "I purged, I puked, I bled 'em, and if they died, I let 'em." Even our immediate predecessors left us nothing but mercury, iodide of potassium, salicylates, bromides and antipyrine.

Of more recent date, the introduction of gland extracts into the pharmacopeia has had its influence on the treatment of hydrocephalus. It is believed, according to the experimental evidence of Frazier,<sup>32</sup> that thyroid extract has a depressant effect on the production of cerebrospinal fluid by the choroid plexuses. This extract has therefore been fed to hydrocephalic children, and a certain number of favorable results have been reported by Frazier,<sup>32</sup> Elsberg,<sup>27</sup> Gray,<sup>36</sup> Litchfield and Dembo,<sup>60</sup> and Mitchell and Zeligs.<sup>64</sup>

As noted, diuretics have long been utilized empirically in cases of "dropsy in the brain." In 1924, Marriott,<sup>61</sup> having shown that, in cer-

tain cases of edema in which the surface tension of the blood was low, fluids tended to pass from the blood into the tissue spaces, was led to try the effect of theobromine sodiosalicylate, which raises the surface tension of the blood, on patients with hydrocephalus. He reported the results in six cases. His experiments were well controlled and showed a favorable response to the drug in all six. In 1925, Mitchell and Zeligs<sup>64</sup> reported a case in which they tried this treatment but without success.\*

#### PHYSICAL AGENTS

Brainard (1825)<sup>8</sup> is said to have been responsible for the introduction of two most unjustifiable procedures. The one was to compress the head by tight bandaging, and the other to inject strong iodine solution into the ventricles, to destroy, as he believed, the secreting epithelial lining. Fortunately, his suggestions were rarely followed and soon entirely abandoned.

The present day fad of treatment by radiation was anticipated by Somma,<sup>66</sup> who is said to have treated, in 1886, five cases by exposing the head to the sun, with improvement in some and cure in the others. This work was never confirmed, and ten years later the German worker, Pott,<sup>76</sup> remarked caustically that "possibly the masculine sun of Italy—they call it *il sole*—is more energetic and healing than ours, who is a lady." Roentgen rays have at the present time eclipsed the sun in this connection. Sgalitzer<sup>82</sup> and Spiegel<sup>87</sup> performed some experiments to prove that exposure of the head, over the choroid plexuses, to the x-ray reduces their function of producing cerebrospinal fluid, and Sgalitzer<sup>82</sup> and Siedamgrotzky<sup>84</sup> advised the radiation of the plexuses instead of their resection.

#### RESECTION OF THE CHOROID PLEXUSES

It is obvious that whether hydrocephalus is due to a failure of absorption or an overproduction of cerebrospinal fluid, the excision of the choroid plexuses should theoretically cure the disease. Practically only the plexuses in the lateral ventricles, however, are accessible, and these only by means of serious transcortical operations which appear too drastic to be justifiable. The operation was actually carried out by Cushing,<sup>17</sup> Hildebrand,<sup>47</sup> Dandy,<sup>18</sup> L  win,<sup>58</sup> Perthes,<sup>73</sup> Polya,<sup>74</sup> Towne<sup>92</sup> and others—on about fifteen patients, of whom three were living at the time when they were reported (by Perthes, Dandy and Polya). It would appear equally logical and much less dangerous to reduce the supply of blood to the plexuses by tying off the carotid arteries.

---

\* Since writing this paper, I have had occasion to test this treatment in three cases of hydrocephalus, with promising results.

## TYING THE COMMON CAROTID ARTERIES

In 1796, Robert Chisholm,<sup>13</sup> about to be graduated in medicine from the University of Pennsylvania, took as the title of his inaugural thesis, "Hydrocephalus internus. . . ." In it he quoted Patterson as suggesting compression of the carotid arteries "in order to obviate a morbid accession of blood to the vessels of the head." The youthful author added, in true schoolboy abandon, "We have no objection to a trial of this practice, *Fiat Experimentum*." One hundred years later, a more mature investigator, Stiles,<sup>14</sup> basing his reasoning on more specific knowledge of the physiology of the circulation of the cerebrospinal fluid, recommended the permanent compression of the carotid arteries by ligature, in order to obviate an accession of blood to the choroid plexuses. Fraser and Dott<sup>11</sup> (1922) followed this suggestion in four cases of the extraventricular (communicating) type of hydrocephalus, with encouraging results in three of them. Fuller<sup>14</sup> (1927) also reported one patient successfully treated in this way. The vessels were tied at two sessions, with an interval of ten days between the two. Fuller recommended the use of silver wire for the ligature, and cautioned against its being tied too rapidly for fear of damaging the vessel wall and causing emboli to form. Following the second ligature, he performed a ventricular puncture.

## PUNCTURE OF THE LATERAL VENTRICLES

Long before antisepsis lent safety to the procedure, heroic doctors attempted to relieve the distress of their patients with hydrocephalus by evacuating the dammed up liquor in the ventricles. Every route was utilized, the anterior fontanelle, the coronal suture, the posterior fontanelle, the nose, the orbit and finally a trephine opening in the skull. Such a puncture is said to have been made on Dean Swift in 1744 (Keen<sup>53</sup>). Le Catt and Remet<sup>50</sup> reported, in 1751, that they had evacuated the fluid in the ventricles of several patients with hydrocephalus, but always with fatal results. Toward the end of the eighteenth century the practice became popular, so that Professor Monro<sup>65</sup> of Edinburgh reluctantly lent it the weight of his authority by saying that "if ever the operation is attempted, the opening should be made with a lancet, and at a part where there is no danger of wounding any large artery or venal sinus of the head." In those days, the puncture of the ventricle was followed almost invariably by death. Since antisepsis has been introduced, however, it has taken its place as a moderately safe procedure to be used as a temporary measure of relief. Indeed, there are numerous reports of cases in which apparent cure or permanent improvement in the hydrocephalus followed repeated or even a single ventricular puncture.

## LUMBAR PUNCTURE

When Quincke<sup>79</sup> (1891) first described the tapping of the spinal subarachnoid space by inserting a hollow needle between the spinous processes of the lumbar vertebrae, he advocated its use in emptying the superabundant fluid from the subarachnoid spaces of patients with hydrocephalus. Since then its use has been common in this connection, and favorable results following one, two or repeated tapplings with the removal of varying amounts of fluid have been reported by Park,<sup>67</sup> Bongianini,<sup>7</sup> von Bokay,<sup>6</sup> Fromowicz,<sup>33</sup> Conto,<sup>14</sup> Howe,<sup>49</sup> Kästner,<sup>51</sup> Bessau<sup>4</sup> and Cassel<sup>12</sup>—to mention only a few. The mechanism of a cure by this means is presumably dependent on the fact that in the cases in question the equilibrium between the formation and the absorption of the cerebrospinal fluid is so slightly disturbed that removing the handicap of excess fluid on one or two occasions allows the balance to become reestablished.

## CONTINUOUS DRAINAGE OF THE VENTRICLES

*External Drainage.*—Following Lister's revolutionary discoveries of 1867, the uncertainty with which even the simplest surgical procedures were undertaken was displaced by greater confidence on the part of surgeons. In 1881, Wernicke proposed trephining the skull and externally draining the lateral ventricles as a means of treating patients with chronic hydrocephalus. In 1886, this suggestion was acted on by Zenner of Cincinnati. Keen,<sup>33</sup> unaware of the previous work on this subject, proposed the same procedure in 1888, and three years later reported at the International Congress of Surgery in Berlin on three cases with this treatment, all ending fatally. From then on, for the next ten or fifteen years, his operation was much in vogue and reports flooded the literature, including those by Pott,<sup>75</sup> Robson, Franks, Broca,<sup>10</sup> Wyss, Hahn, Dujan, Kocher, Power,<sup>77</sup> McCosh, Trinkler<sup>93</sup> and others. Most of these attempts, however, also ended in failure. In spite of antiseptic and aseptic precautions, some patients died of infection, others of intercurrent disease while still under treatment, a few as a result of the operation itself, some apparently because the release of the intracranial pressure was too rapid, and still others for no demonstrable reason.

*Drainage into the Subcutaneous and Subarachnoid Spaces.*—In order to permit the drainage to continue permanently, to avoid infection and to avoid a too rapid discharge of fluid, the next logical step was to devise a method of internal drainage of the ventricles. This was first accomplished by Miculicz, who, in 1893, presented to the German surgical congress a child in whose lateral ventricle he had inserted a nail-shaped mass of glass wool, the head of the "nail" coming to lie under the little osteoplastic flap which was closed tightly over it. The child survived

the operation and eventually its hydrocephalus ceased to progress. Later, according to Henle <sup>45</sup> and Kausch,<sup>52</sup> Miculicz devised a tube made of gold (fig. 1), which he inserted in two stages—first placing the perforated disk (fig. 1 b) under the scalp, and then passing the flanged tube (fig. 1 a) through a hole in the disk and in the skull into the ventricle. Writing from the Miculicz clinic in 1896, Henle seemed hopeful of the results obtained to that time, and cases began to be reported in the literature in which this method or some modification of it had been used.

In 1898, Sutherland and Cheyne <sup>53</sup> reported three patients in whom they accomplished internal drainage by passing some strands of catgut into the ventricle and inserting the free ends under the dura. In one case it failed. One patient began to improve, but died afterwards of meningitis. The third was alive and seemed better at the time of the report. In the discussion of their paper, Dr. H. J. Stiles also reported the cases

Fig. 1.—Miculicz' gold tube for use in draining spinal fluid from the ventricles in hydrocephalus (after Henle: *Mitt. a. d. Grenzgeb. d. Med. u. Chir.* **54**:1859, 1927). *A* represents the phlanged tube, *B* the perforated disk and *C* the assembled tube and disk.

of three patients operated on in this way. All of the patients died, and he discredited the procedure.

The next year, 1899, Dehler <sup>24</sup> reported a failure of the gold-tube method owing to stoppage of the tube. Schramm <sup>50</sup> also reported a case during that year in which drainage was secured by means of catgut. The patient improved for three weeks, then he was lost sight of.

In 1903, Senn <sup>81</sup> described a case in which he drained the ventricle into the subdural space by means of a perforated rubber tube (fig. 2). The child showed improvement for eight days. The tube was then removed, and the same night hyperthermia occurred followed by death.

A case treated with some measure of success by Miculicz' original glass wool "nail" was reported by Horsley <sup>48</sup> in 1906.

Speaking before the Berlin Medical Society in 1908, Krause <sup>56</sup> described a modified Miculicz tube consisting of gilded silver. This tube, intentionally too long, is passed through a small hole in the skull and through the brain into the ventricle. After this, it is advanced

another 0.5 cm. in order to allow for thickening of the cortex as the ventricles shrink. The free end of the tube is then pinched off about 1 cm. above the bone and is split down on two sides and two tongues bent down against the skull at right angles to the tube. These may then be fastened by sewing the pericranium over them. Krause reported four cases in which this procedure was tried; in one of these there seemed to be some improvement eight months after the operation.

In 1909, Taylor<sup>50</sup> reported a case in which drainage of the ventricle into the subdural space was effected by the use of chromic catgut wrapped in Cargile membrane, with satisfactory improvement for fourteen months; then the child died of gastro-enteritis. He also mentioned another case in which he used a vein from the arm of the patient's father for a drain.

Fig. 2.—Drainage of the ventricles into the subaponeurotic layer of the scalp by means of a perforated rubber tube (after Senn: *Alienist & Neurol.* 24:317, 1903).

Andrews<sup>1</sup> (1911) demonstrated that a glass tube can be used in place of a gold one in the Miculicz operation, and reported such a case in which improvement was shown for five years.

Pussep<sup>75</sup> (1912) made a modification in Krause's modification of Miculicz' method by sewing the tongues of the silver tube to the dura instead of the bone, believing that in this way the ventricular fluid might reach the subarachnoid, as well as the subcutaneous, spaces. He reported ten cases with a certain degree of improvement in nine of them.

Hudson<sup>50</sup> proposed the use of a coiled silver wire tube in the ventricle connected with a fan-shaped silver wire mat lying under the temporal muscle.

Sharpe<sup>52</sup> (1917) reported forty-one cases in which he tried to produce drainage by means of linen threads (fig. 3). These he inserted into the ventricle in the case of the noncommunicating type of hydrocephalus.

and simply under the dura in the case of the communicating type. In both types, the free ends of the threads were led to the subcutaneous tissue. Thirteen of his patients died within thirty-six hours after the operation. Five others failed to improve as a result of it; twenty-three improved in varying degrees; five improved remarkably.

Still another method involving the same principle was proposed by Hildebrand<sup>17</sup> in 1923. According to his method, the roof of the orbit is laid bare through an incision in the eyebrow, a piece of bone 1.5 by 2 cm. is removed about 1 cm. inside the orbital ridge. A hole is then cut in the dura, the anterior horn of the ventricle is punctured, the wound is closed and the patient sat up to favor drainage. One child on whom he carried out this procedure improved for a time. The symptoms recurred, however, and the operation had to be repeated—first on the

Fig. 3.—Drainage of the ventricles or the subarachnoid space, linen threads being used as the drain (after Sharpe; *Am. J. M. Sc.* **153**:563, 1917). *A* indicates temporal muscle; *B*, temporal fascia; *C*, opened dura; *D*, sylvian fissure; *E*, lateral ventricle; *F*, linen threads; *G*, zygomatic arch; *H*, parietal crest.

other side, then on the original side. Sokolowski and Irger<sup>85</sup> (1925) used this operation in six cases, but with rather discouraging results. They believed that the absorptive area in the fatty tissue of the orbit it not large enough, and proposed a drainage of the ventricle into the fatty tissue of the cheek—the globulus adiposus of Bichat, between the cheek muscle and the masseter, which connects with the lymphatics of the neck. Such a pathway is produced by making a subtemporal decompression, drawing up a strip of the fat still attached by the one end to the area just mentioned, and inserting the free end into the temporal horn of the ventricle. They operated on four patients by their method. Two were slightly improved.

In 1924, Koljubakin<sup>84</sup> described a modification of still another method of draining the ventricle into the subcutaneum, originally

devised by Wenglowksy in 1913, consisting of a plastic tube or strip prepared from the dura which remains attached at one end. The free end is plunged transcortically into the ventricle.

Finally, in 1926, Kosyrew,<sup>55</sup> in view of the work of Linberg and especially Sokolowsky in the use of strips of omentum for various purposes in those cases in which delicate epithelial pathways are of value, utilized omental strips to drain the excessive ventricular fluid of patients with hydrocephalus to the subdural and subarachnoid spaces. He reported the cases of eleven patients on whom the operation had been performed, of whom two died and nine showed varying degrees of recovery.

Another method of leading the ventricular fluid into the subarachnoid space deserving special mention because of its widespread use was planned by the German neurologist Anton,<sup>2</sup> and carried out by his surgical colleague, von Bramann,<sup>9</sup> in 1908. This is the well known puncture of the corpus callosum (*Balkenstich*). Although much more popular than many other methods, it is gradually being discarded like them because, in the first place, the puncture hole in the corpus callosum does not stay open long, and because many patients, especially those with the communicating type of hydrocephalus, fail to be benefited by such an opening. Denk<sup>25</sup> (1927) collected seventy-seven cases of hydrocephalus from the literature which had been treated by the callosal puncture. Among them were only six operative fatalities, but the results in the others were, on the whole, unsatisfactory.

A more recent variation of the Anton-Bramann operation is the one proposed by Dandy<sup>21</sup> (1922), in which, through a frontal approach, he cuts a window in the anterior wall of the third ventricle, thus not only releasing the dammed up fluid in the ventricular system, but establishing an opening for the fluid into the cisterna chiasmatica. At the time of his writing, he had done this operation on six patients, but was not ready to report on them.

In the noncommunicating type of hydrocephalus, in which the obstruction is at the foramina of Luschka and Magendie, a suboccipital operative approach and the freeing of adhesions, or the establishment of a new outlet through the posterior velum, would be a logical procedure. As early as 1893 it was attempted by Alfred Parkin.<sup>68</sup> The obstruction in his case was due to a tuberculous exudate, and the patient died. In 1895, however, Glynn and Thomas<sup>35</sup> successfully accomplished this operation. In 1911, Andrews<sup>1</sup> described a patient on whom Murphy had operated ten years before, making a window in the posterior velum. This boy did well for five or six years; then his symptoms gradually returned. Two more patients were reported successfully treated in this way by Dandy<sup>20</sup> in 1921, with, of course, a much modernized technic.

When the obstruction was at the aqueduct of Sylvius, as shown by ventriculography, Dandy<sup>10</sup> (1920) carefully forced a small sound through the iter, under vision; then he put a perforated rubber tube into the aqueduct to help the canal reform. Two or three weeks later, at a second operation, the tube was removed. He reported on two patients one of whom died of pneumonia seven weeks after the operation. The other was doing well one year afterwards. Litchfield and Dembo<sup>60</sup> (1922) attempted this operation, but their patient died. Fraser and Dott (1922) also made use of this procedure.

Fig. 4.—Drainage of the ventricles into the longitudinal sinus (right) or the subarachnoid space (left) by means of a transplanted vein (after Payr: Arch. f. klin. Chir. 87:701, 1908).

*Drainage into the Blood Stream.*—Since the natural outlet of the cerebrospinal fluid is into the blood stream, and since the pressure in the cerebrospinal fluid spaces, as shown by Dixon and Hallburton and Wegforth and Weed, is always slightly in excess of the venous pressure, Payr<sup>71</sup> (1908) decided to connect the hydrocephalic ventricles with the longitudinal sinus (fig. 4), the jugular, or the common facial veins. His technic was elaborate, but, briefly, consisted of transplanting a vein from the patient himself, or better, some adult donor. One end of the vessel was inserted into the ventricle, while the other was sewn

into the sinus. The vein was so placed that the valves opened only to a stream flowing from the ventricle to the sinus. His first five attempts failed. He ascribed this failure to the collapsibility of the transplanted vessels, and, in 1911, proposed the use of hardened calves' arteries within a venous sheath. He reported fifteen patients at this time<sup>72</sup> only eight of whom had been treated by transplantations of vessels. Unfortunately, he lumped his results, so that one cannot know how these eight fared as compared with those he had treated in other ways. Seven of the fifteen died. Of the eight surviving ones, four showed some improvement.

Enderlen<sup>28</sup> (1911) reported a case in which he transplanted the fresh anterior tibial artery between the ventricles and the superficial

Fig. 5.—A Y-shaped vein to be used as a conduit for cerebrospinal fluid from the subdural space into the blood stream. *A* represents the vein after excision; *B*, the vein prepared for transplantation and *C*, the vein sutured into place under the dura (after McClure: Bull. Johns Hopkins Hosp. 20:110, 1909).

temporal vein. This worked nicely for a while, then it became blocked and the symptoms returned.

McClure<sup>62</sup> (1909), presumably for cases of communicating hydrocephalus, proposed drainage of the subarachnoid space into the jugular by means of a transplanted vein (fig. 5). He made clever use of Y-shaped pieces of vessel, which he succeeded in transplanting five out of six times in dogs. Unfortunately, his only case in man died of hyperthermia after the operation.

Cushing<sup>17</sup> spoke of having attempted a drainage of the ventricular fluid into the blood stream by the placement of a specially devised silver tube that led from the dilated third ventricle through the corpus callosum directly into the longitudinal sinus. But the results were inconclusive.

Haynes <sup>37</sup> (1913) hit on a simple method of connecting the subarachnoid spaces and the blood stream. By way of a suboccipital approach, he laid the dura bare, then inserted one end of a rubber or silver tube through a slit in the dura into the cisterna magna. The other end was then similarly passed into the lower end of the longitudinal sinus or torcula. His first paper contained reports of two fatal attempts, and later papers <sup>38, 39</sup> showed increased skepticism regarding the value of the method.

#### CONTINUOUS DRAINAGE OF THE SPINAL SUBARACHNOID SPACE

The large majority of cases of hydrocephalus occurring in young children, as attested to by Cushing,<sup>17</sup> Elsberg<sup>27</sup> and others, are of the communicating type. One turns, therefore, with interest to the discussion of methods intended specifically to cure this variety of the condition. Naturally, all methods aiming at the drainage of the spinal rather than the cranial subarachnoid space, whether intentionally or not, could be effective only in the communicating type of hydrocephalus.

The earliest attempt at a prolonged drainage of the spinal subarachnoid space was by Quinke<sup>79</sup> (1891), who advised using a lancet point on a lumbar puncture needle and moving it back and forth during its passage through the dura in order to slit this membrane and permit a seepage of fluid through it to the lymphatic spaces of the spinal muscles and subcutaneous tissue. This method was again advocated later (1912) by Fromowicz.<sup>33</sup>

A little known, but more ambitious, effort to accomplish the drainage of the spinal canal was mentioned in an editorial in the *New York Medical Journal* (1:902, 1898). Two cases were briefly described, in which the patients had been treated by A. H. Ferguson. He removed the arch of the fifth lumbar vertebra, then pulling the cord aside, drilled a hole through the body of the vertebra toward the peritoneum. Through the hole he passed the loop of a U-shaped silver wire toward the peritoneum and bent the free ends downwards toward the cauda equina. His first case died soon after the operation, the second one improved for three months, but then died of bronchopneumonia.

Nicoll (1898) suggested drawing up the free edge of the omentum through a paravertebral approach to the peritoneum, and at the same operation attaching this to a defect in the spinal dura. In 1905,<sup>66</sup> he carried out this operation, but when he wrote his report, insufficient time had elapsed since the operation to allow him to judge of his results.

In 1905, also, Cushing<sup>15</sup> mentioned six patients treated by his method of anastomosing the spinal subarachnoid with the peritoneal or retroperitoneal spaces. The results in three of the patients he looked on as encouraging. His operation, after some preliminaries to establish

the presence of a communication, etc., consists of a combined laminectomy and laparotomy during which a hole is drilled in the body of the fourth lumbar vertebra, and a silver canula inserted. The latter is composed of a female half put in from the posterior aspect, and a male half forced in from the peritoneal side. In 1908, Cushing<sup>16</sup> mentioned twelve patients on whom he had operated in this way with "a considerable measure of success." Unfortunately, two or three infants did well for a week or two after the operation and then died. They proved at autopsy to have died of intussusception.<sup>17</sup> Believing that the presence of the pituitary secretion contained in the spinal fluid may have caused a disturbance in the normal peristaltic activity of the intestines, and thus have been the indirect cause of the death of these patients, he soon abandoned his operation.

Fowler<sup>29</sup> practiced the Cushing technic, and reported two cases in which the patients were treated according to this method in 1909. The first patient was an infant, aged 8 months, who withstood the operation well. Six months later, at the time of the report, the hydrocephalus was definitely arrested and the child developing normally. At the age of 4,<sup>30</sup> the child was healthy and even brighter mentally than the average for his age. When he was 12 or 13 (the author recollected the age indistinctly) the boy was again reported physically normal and mentally above the average. Fowler's second case was that of a congenitally syphilitic child, who proved to have plastic adhesions above the level of the tube. It died soon after the operation.

Of late years, the most persistent exponent of the drainage of the spinal canal in the treatment of hydrocephalus has been the German surgeon, Heile.<sup>40</sup> In 1908, a child who had been operated on for meningocele during the second day of life, began, at 5 months, to develop hydrocephalus. Temporary measures failed to give relief, and when the child was 8 months old Heile, entering through the old scar, reached the peritoneal cavity in the paravertebral region. He pulled out a loop of intestine and sewed the serous surface to a slit in the spinal dura (fig. 6). Because of an error, as the author believed, in the post-operative care, the patient died twenty hours after the operation. Autopsy did not reveal any cause of death.

Two years later,<sup>41</sup> he reported another case. This was a child aged 2 days with spina bifida and hydrocephalus. This time, he amputated the sac, and at the same operation drained the spinal canal by means of silk threads leading from the dura to the peritoneum (fig. 7). Immediately after the operation, he kept the child's pelvis elevated above the level of its head in order to permit the wound to heal. Ten months after the operation, the child was entirely well. Two years later, it died of an intercurrent infection.

Fig. 6.—The serous surface of an intestinal loop: (*A*) attached to a defect in the dura; (*B*) to lead the cerebrospinal fluid into the peritoneal cavity (after Heile: *Deutsche med. Wchnschr.* 24:1468, 1908).

Fig. 7.—Silk threads (*A* to *B*) used to conduct the cerebrospinal fluid stream from the end of a meningocele sac into the peritoneum (after Heile: *Berlin klin. Wchnschr.* 47:2298, 1910).

In 1914, Heile<sup>42</sup> received as a patient a boy aged 8, of normal intelligence, but with an extremely large head that had been increasing in size since birth. The boy had never walked and was suffering from spastic contractions of the extremities. Repeated lumbar punctures with the removal of large quantities of fluid (from 100 to 130 cc. at a time), and puncture of the corpus callosum failed to give relief. The author then tried to connect the spinal canal with the abdominal cavity by means of a transplanted saphenous vein. This also failed, due to the collapse of the vessel. The latter operation was then repeated on the other side,

Fig. 8.—The establishment of connections between the spinal subarachnoid space and the peritoneal cavity. *A* represents a transplanted vein; *B*, a rubber tube; *C*, the place of entrance into the peritoneum (the triangle of Petit) and *D* the dura (after Heile: *Arch. f. klin. Chir.* **105**:501, 1914).

this time a rubber drainage tube being used (fig. 8). Five months afterward, the boy walked for the first time in his life, and the head, on one side at least, was not any longer transilluminable as it was before the operation.

Heile continued his efforts to treat hydrocephalus by draining the spinal subarachnoid space. In 1925,<sup>43</sup> he reported that the boy operated on in 1914—nearly twelve years before—was still living and well. The only difficulty was the fact that about once a year the tube was extruded

as a foreign body and had to be renewed. Since 1914, he had done such operations on four more patients. One of these was still living and doing well eight years after the operation.

At the time of this last report, Heile published still another method. This consisted of performing a unilateral nephrectomy followed by an anastomosis of the kidney pelvis to the spinal subarachnoid space. Drachter,<sup>20</sup> on hearing Heile's report, stated that in 1917 he had already done such an operation on an infant 6 months old, who died from an undeterminable cause in forty-eight hours. In 1927, Heile<sup>14</sup> was able

Fig. 9.—Whole thickness graft of skin sutured under the desired tension directly on muscle tissue; the line of the skin incision and the retraction of the skin over the muscle may be noted (after Davis and Traut<sup>23</sup>).

to report on four children in whom this dura-ureter anastomosis had been effected. One had died of pneumothorax, but the other three were doing well.

#### AUTHOR'S METHOD

In 1926, Davis and Traut<sup>23</sup> published the following experiment: Dogs, under ether anesthesia, were shaved and the skin of the abdomen carefully cleansed. The experimenters then cut out a strip of skin and implanted it under the rectus fascia. The piece of skin was sewn directly to the muscle by closely placed sutures at a tension corresponding to that which was exerted on it in its original position (fig. 9). The

edges of the fascia were sewn over it, one at a time, the second overlapping the first, thus forming a double layer. Finally subcutaneous tissue and skin were carefully closed (fig. 10).

They found that, within twenty days, the epidermis had grown outward from all sides of the strip of buried skin and covered the overlying double layer of fascia. The result was an epidermis-lined tube with firm strong walls (fig. 11). In addition to tubes, they were able to produce oval or, indeed, any shape of sacs up to 6 cm. in diameter. In the cases of sacs 6 cm. or more in diameter, necrosis from too great tension resulting from secretion of the skin glands began before epithelialization was complete. After forty days, the tension was sufficient to produce necrosis in tubes of any size, unless evacuation of the secretion was accomplished.

This experiment I have repeated numerous times, and always with uniformly favorable results. Guided by the experience of the original authors, I waited from twenty-eight to thirty days after the operation before examining the transplant, and invariably found a beautifully

Fig. 10.—Overlapping muscle fascia over the graft; the line of closure of the skin should be noted (after Davis and Traut<sup>23</sup>).

formed epidermis-lined tube with firm strong walls, the strength of which could be increased by dissecting off with it a few millimeters of rectus muscle to which it had grown adherent.

Such a tube, it seemed to me, could advantageously supplant any homotransplants or heterotransplants of veins or arteries, or rubber, glass or collodion (Lambert) tubes in any of the various attempts to cure hydrocephalus by connecting the spinal or cerebral subarachnoid spaces with one of the body cavities. Its advantages are that, within the limits stated, it can be made any desirable length and diameter; its walls are strong and noncollapsible, and it is autogenous.

Since the majority of the cases of hydrocephalus are communicating, my method is aimed at this type of the condition. The procedure may be described as follows:

After studies have been made, on admission, to determine the existence of a communication of the spinal subarachnoid space with the ventricles, the primary operation should be carried out. This should consist of the transplantation of a strip of skin, 1.5 cm. wide and as long as possible, under the rectus fascia. In experiments on dogs, I found it

useful to make the ends of the strip of skin somewhat wider than the main portion, in order to have a funnel effect for implantation.

This procedure is a rather extensive and tedious one, but being wholly superficial, should be borne well even by the usual puny hydrocephalic infant.

Fig. 11.—Appearance of epithelium-lined tube, thirty-two days old, being raised from the rectus muscle; *A* represents a cross-section of this tube, showing the epithelial lining, which has a rough appearance because of exfoliated epidermis and the growth of hair (after Davis and Traut<sup>21</sup>).

While waiting for the tube to form, every effort should be made to improve the child's condition before the second operation. Repeated lumbar puncture or ventricular punctures should be done and treatment

with theobromine sodiosalicylate carried out after the manner of Marriott.

At the second operation, four weeks after the first, the epidermis-lined tube is dissected out through the scar of the previous incision, with the greatest dispatch possible, since the muscle adherent to it tends to cause it to shrink. The funnel-shaped lower end of the tube is implanted into the peritoneum as far laterally as possible—the triangle of Petit may be reached by retracting the skin laterally at the lower end of the wound. A 2 inch (5 cm.) incision is then made over the lumbar spine. By passing a curved clamp under the subcutaneous fascia from here into the lower end of the first wound, the upper funnel-shaped end of the epithelial tube may be grasped and pulled through to the back. A laminectomy should next be made over perhaps two vertebrae, and the tube-end anastomosed with a slit in the dura. The child's hips should be elevated above the level of its head before the dura is opened in order to prevent the fluid from escaping too fast. Both incisions should then be closed and a small drain put into the lower end of the first wound because of the large dead space left subcutaneously.

While the opportunity to carry out this operation on a human being has not as yet presented itself to me, I have gone through the maneuvers several times in dogs. The technical procedure is certainly not difficult, and should be less so in the human subject. In the dog, even over the abdomen, the skin is hairy, and the growth of hairs within the tube tends to narrow its lumen. In the second place the vertebral laminae are relatively much thicker in the dog than in the human being. Again, the dog's dura lies so close on its leptomeninges that its spinal subarachnoid space is hardly more than a potential one. Finally, in the absence of hydrocephalus—so far only healthy dogs have been used—insufficient stimulus exists to keep the ends of the tube open.

In view of these handicaps when healthy dogs are subjected to these procedures, the following protocol is sufficiently encouraging not only to cause one to continue the experiments—perhaps previously producing communicating hydrocephalus in the dogs by the method of Dandy<sup>18</sup>—but eventually to apply the operation in suitable cases in man:

On April 12, 1928, a young female airdale was placed under morphine and ether anesthesia. After the skin over the abdomen had been shaved and washed with soap and water, benzene, alcohol and ether, it was painted with mercurochrome-220 soluble.\* A strip of skin 1 cm. wide, except at the two ends where it was allowed to flare a bit, and about 20 cm. long was implanted under the rectus fascia by the method of Davis and Traut. The dog recovered promptly from the anesthetic and

---

\* Davis and Traut recommend the following mixture: Alcohol, 95 per cent, 55 cc.; acetone, 10 cc.; mercurochrome, 2 Gm.; distilled water, 35 cc.

almost immediately returned to normal activity. On April 20, 1928, the wound was healed by first intention, and the animal was in excellent condition.

On May 10, 1928, the second operation was performed under morphia and ether anesthesia. The skin was prepared as before. Through the scar of the previous wound the skin tube was dissected out, and the lower end was pulled subcutaneously through an incision over the lumbar spine. A laminectomy was done, the dura opened and the free end of the tube anastomosed to it. Both wounds were closed.

On May 17, 1928, the animal was in excellent condition. Both wounds were healed, except for a slight stitch abscess in the lower end of the abdominal one.

Fig. 12.—The cordlike outline of the grafted skin tube is brought out by the extension of the animal.

There was a cordlike bulging under the skin corresponding to the position of the transplanted tube (fig. 12).

On June 21, 1928, the condition of the animal continued satisfactory. On the day of writing this report, the animal was killed by an overdose of ether, and the transplanted tube was examined. It was found to be well preserved and healed into place without excessive scar tissue. The lumen was patent throughout its extent. The spinal end was still in communication with the subarachnoid space, although the opening was only about 1 mm. in diameter. The peritoneal terminal of the tube was closed over by a delicate layer of omentum.

## COMMENT

Hardly any other pathologic condition has been accorded more determined attention on the part of the medical profession with the aim of finding a cure for it than has hydrocephalus. And in hardly a single other condition have cures been so illusive or so often wrecked on purely mechanical obstacles. Yet the outlook is certainly not hopeless. Especially during the past twenty years, during which surgery of the nervous system has improved so remarkably, frequent reports of cures by surgical means have appeared.

Since the mechanics of the circulation of the cerebrospinal fluid and their pathologic alterations in hydrocephalus have been better understood, the failures based on the choice of a wrong type of operation for a given case have markedly decreased. The difficulty at the present time with the operations, though logically conceived in relation to the mechanism of the liquor circulation, is that they often fail to take into consideration the reaction on the part of the body toward the newly established pathways and toward the material utilized in establishing these pathways. For example, the various operations to drain the ventricular fluid into the subaponeurotic tissue of the scalp are logical in certain types of cases of hydrocephalus; their failure comes about through the fact that the absorptive power of the subcutaneous tissue is rapidly lost. Cushing explains this loss in the following way:

The scalp at first (immediately following the operation) becomes widely edematous, but in the course of a few days the edema gradually subsides, and finally a circular pool of fluid a few centimeters in diameter is all that remains. This disc-like subaponeurotic pool, which continues in free communication with the ventricle, becomes promptly lined with a layer of glistening serosal cells, like those lining the dura, which are impervious to the further escape of fluid into the tissues.

The connection of the cerebrospinal fluid spaces with the blood stream by means of transplanted vessels is also theoretically correct. But the vessels collapse or the artificial tubes behave like foreign bodies.

The most promising results thus far obtained have been those following the establishment of a connection between the spinal subarachnoid space and the peritoneal cavity in the communicating type of hydrocephalus. Cushing's results, although never published in extenso, have been promising. Fowler's case, done according to Cushing's technic, has been a complete success. Heile's reports have been the most hopeful in recent literature.

Several difficulties, however, remain to be solved. In the first place, is it physiologically safe to permit the spinal fluid to pour into the peritoneal cavity? Dr. Cushing's experience many years ago, already mentioned, when two or three babies died of intussusception following his operation, led him to believe that the procedure was not safe because of the presence of pituitary secretion in the cerebrospinal fluid. At that

time, the demonstration of pituitary substance in the cerebrospinal fluid was new, and its importance may have been overestimated. It is now known that the quantity of pituitary secretion in the cerebral fluid is small. Moreover, Meztretzat<sup>63</sup> recently showed that while traces of it are present in the fluid of the ventricles, by the time the liquor has reached the spinal subarachnoid space no trace of pituitary substance is demonstrable. There have been, moreover, only two or three cases in which death followed as a result of intussusception after the spinal fluid had drained into the peritoneum; whereas at least twenty cases have been reported in the literature in which such an operation was done.

The large percentage of cures reported among cases of communicating hydrocephalus treated by drainage of the spinal subarachnoid space into the peritoneum must be taken as an answer to the possible objection that any tube sutured into the dura fails, in the strictest sense, to drain the subarachnoid, as distinct from the subdural, space. During the operation an opening is, of course, made in the arachnoid membrane. But the breach repairs itself rapidly. It is a fact, however, that a certain amount of fluid circulates in the subdural space, showing that the thin arachnoid membrane is permeable to the fluid. Thus a pathway leading from the subdural space indirectly drains off the subarachnoid fluid as well. A similar permeability may be demonstrated through the thin peritoneal or omental membrane, which rapidly closes over the peritoneal opening of any connecting tube.

Granting the safety of the procedure on physiologic grounds, the choice of the type of operation must next be considered. Heile's latest method of taking out a kidney, which, by the way, avoids the diversion of the fluid into the peritoneum, is, in the first place, too drastic, and in the second, lays the cerebrospinal fluid spaces open to all the dangers of infection to which the genito-urinary system is subject. Thus far the simplest procedure, and the one which promises the most, is the one of Heile in which he connects the spinal canal with the peritoneum by means of a rubber tube (see fig. 8). The only difficulty is that the tube is not tolerated by the system. The operation suggested by me is applicable only to the communicating type of hydrocephalus. It, also, consists of the establishment of a communication between the spinal subarachnoid space and the peritoneal cavity. The connecting pathway, however, is a strong-walled, epithelium-lined, autogenous tube prepared from the patient's own skin.

# CEREBROSPINAL FLUID CHANGES IN COMPOSITION AND DRAINAGE AFTER INTRAVENOUS ADMIN- ISTRATION OF VARIOUS SOLUTIONS\*

R. G. SPURLING

An isolated clinical observation led to the study, in the experimental laboratory, of some of the effects produced in the cerebrospinal fluid by continuous subarachnoid drainage. The case in question was one of meningeal infection; treatment consisted in creating a lumbar subarachnoid fistula. The intake of fluid was kept constantly between 4000 and 5000 cc. per twenty-four hours. The drainage of spinal fluid was estimated as 800 or 1000 cc. per day; this figure was obtained by weighing the dressings before and after saturation. The urinary output during the time that the spinal fluid escaped was from 1600 to 2000 cc. every twenty-four hours. After the spinal fistula healed, it was found that the urinary output increased approximately 1 liter, when the total intake of fluid and the other conditions remained essentially the same. These observations led to the belief that large quantities of water and perhaps of other inorganic and organic substances are eliminated through the cerebrospinal fluid spaces, in the presence of free drainage.

Various observers<sup>1</sup> have concluded, chiefly from deduction, that there is a direct relationship between the water content of the circulating blood and the amount of cerebrospinal fluid produced. These deductions, in the main, have been based on studies of the pressure of the cerebrospinal fluid after the forced administration of fluid. These pressure changes themselves, however, since the cerebrospinal fluid system is closed, may produce changes in both the production and the reabsorption of the fluid. A more direct estimation of the amount of cerebrospinal fluid formed under varying conditions of water intake may be arrived at by the study of the quantity of fluid drained, especially when there is continuous drainage through a large needle which reduces changes in intracranial pressure to a minimum. Another advantage of studies of drainage over those of pressure is that rela-

tively large amounts of fluid are available for physical and chemical studies without interference in any way with the experimental conditions. Such analyses give important information about the nature of the mechanism responsible for the production of cerebrospinal fluid.

The attempt has been made, therefore, by the intravenous injection of solutions of different concentrations, to correlate the variations in quantity, specific gravity and chemical composition of the cerebrospinal fluid drained with the changes that occur in the blood.

### METHODS

All the experiments were performed on dogs. Sodium barbital, 0.3 Gm. per kilogram of weight, was injected intravenously one hour before the operation.

Continuous drainage of cerebrospinal fluid was instituted at the *cisterna magna*. The occipito-atlantoid ligament was exposed by a straight midline incision. The heavy muscles of the neck were separated by a small self-retaining retractor. A no. 10 gage needle (4 cm. long with a short bevel) was carefully inserted through the midline into the subarachnoid space. Fluid escaped continuously throughout the experiment. When the first large quantity of fluid escaped, it was collected in small graduated cylinders (5 cc.) at intervals of five minutes. After each period, the fluid drained was measured and recorded; then it was transferred to small clear test tubes, which were tightly stoppered. Determinations of the specific gravity and such chemical analyses as were made were done within two hours after the fluid was collected.

Simultaneous readings of the specific gravity were made on the whole blood in some of the experiments. All determinations of the specific gravity, whether of the blood or of the cerebrospinal fluid, were made by the falling drop method of Barbour and Hamilton,<sup>2</sup> which has been found to be reliable and simple. It is accurate to one point in the fourth decimal place in the hands of those experienced with the method.

The intravenous injections used were: a 50 per cent dextrose solution, 15 per cent, and 0.45 per cent sodium chloride solutions, Ringer's solution and distilled water, all prepared with chemically pure materials dissolved in fresh double distilled water.

### RESULTS

For the sake of clarity, the results are given and discussed under headings corresponding to the type of solution injected into the bloodstream: isotonic, hypotonic and hypertonic.

*Isotonic Solutions.*—When Ringer's solution was injected into the blood stream there was a prompt increase in the amount of cisternal fluid drained. The diuresis produced was in direct proportion to the amount of the solution and the rapidity with which it was given. The injection of 125 cc. of Ringer's solution (6 cc. per kilogram) during a period of twelve minutes produced a moderate increase in the drainage; the output of cisternal fluid approximately doubled during the period

which began with the injection and ended five minutes later (fig. 2). When large amounts of Ringer's solution (475 cc. during a period of from five to six minutes) were given, the drainage of fluid was increased from fourfold to fivefold in ten minutes, including the time of injection. This increase was of short duration, the normal rate of flow being reestablished in from fifteen to twenty minutes (figs. 1 and 2).

The intravenous injection of 475 cc. of Ringer's solution in five minutes produced a 12 per cent dilution of the whole blood. The maximum dilution occurred within the five minute period of the injection. As soon as the dilution of the blood began, the increase in drain-

Fig. 1.—Changes in the specific gravity of the whole blood and the cerebrospinal fluid drained after the intravenous injection of Ringer's solution in a collie dog weighing 22 Kg. The line of solid circles represents the specific gravity of the blood; the line of open circles, the cerebrospinal fluid drained. In this and the following charts, the numbers on the left side of the vertical scale measure the specific gravity, and those on the right side, the number of cubic centimeters; the horizontal scale gives the numbers of minutes required for the experiment. The heavy black area along the horizontal scale represents 475 cc. of Ringer's solution.

age started. Both the dilution and the dicephalesis reached the maximum at about the same time (fig. 1).

When the drainage was most rapid and the blood most diluted, the specific gravity of the cisternal fluid was lowest (figs. 1 and 2). This would indicate that a substance, presumably newly formed fluid, had

entered the cerebrospinal spaces which contained more water and less solids than the fluid contained before the injection began. These changes were to be expected since the blood contained more water, as shown by the 12 per cent dilution during this period.

*Hypotonic Solutions.*—Small quantities of distilled water given intravenously (up to 7 cc. per kilogram) produced little increase in the drainage of cisternal fluid (figs. 3 and 5). The increase occurred regularly but was small in amount. The magnitude of the response

Fig. 2.—Changes in the specific gravity of the cerebrospinal fluid and the amount drained after the slow and rapid administration of Ringer's solution administered intravenously to a long-haired cur, weighing 20.4 Kg. The line of open circles represents the amount of cerebrospinal fluid drained; the line of solid circles, the specific gravity of the cerebrospinal fluid. The three black areas along the horizontal scale indicate, respectively: 125 cc. of Ringer's solution, 475 cc. of Ringer's solution, and 40 cc. of distilled water.

would not compare in any way to that obtained from equal amounts of Ringer's solution or hypotonic sodium chloride solution.

The specific gravity of the blood was little affected by the injection of small amounts of distilled water (7.5 cc. per kilogram). There was a slight dilution for a period of fifteen minutes, the maximum dilution being 4 per cent.

The specific gravity of the cerebrospinal fluid in these experiments did not show any recognizable change (figs. 3 and 5).

It would seem, therefore, that small amounts of distilled water (up to 7 cc. per kilogram) injected into the blood stream produce little change in the blood and cisternal drainage and no recognizable change in the specific gravity of the cerebrospinal fluid. Why distilled water in this amount failed to influence these factors, when similar amounts of Ringer's solution and half normal sodium chloride solution did so, I am unprepared to say at this time.

Fig. 3.—Changes in the specific gravity of the cerebrospinal fluid and amount drained, after the administration of distilled water and a 50 per cent dextrose solution intravenously to a long-haired cur weighing 20.4 Kg. The line of open circles represents the amount of cerebrospinal fluid drained; the line of solid circles, the specific gravity of the cerebrospinal fluid. The black areas along the horizontal scale represent, respectively: 40 cc. of distilled water, and 100 cc. of a 50 per cent solution of dextrose.

Hypotonic solutions of dextrose and sodium chloride produced the same type of response in the blood and cerebrospinal fluid as did Ringer's solution (fig. 4). The increase in cisternal drainage depended directly on the amount of the solution and the rapidity with which it was given.

*Hypertonic Solutions.*—The intravenous administration of a 50 per cent dextrose or a 15 per cent sodium chloride solution produced a temporary increase followed by a profound decrease in the amount of cisternal fluid drained. Five cubic centimeters per kilogram of a 50 per cent solution of dextrose caused such a marked fall in the output of fluid that prolonged jugular pressure was required to obtain sufficient fluid for analysis (figs. 3 and 4). Seven cubic centimeters per kilogram of

Fig. 4.—Changes in the composition, specific gravity and drainage of the cerebrospinal fluid after the intravenous administration of Ringer's solution, and solutions of dextrose and sodium chloride to a long-haired cur weighing 20.4 Kg. The line of solid circles indicates the amount of cerebrospinal fluid drained; the line of open circles, the specific gravity of the cerebrospinal fluid, and the line of broken circles, the number of milligrams of sugar in the cerebrospinal fluid. The black areas along the lower scale represent, from left to right: 400 cc. of Ringer's solution, 100 cc. of a 50 per cent solution of dextrose, and 200 cc. of a 0.45 per cent solution of sodium chloride.

a 15 per cent solution of sodium chloride, after a primary increase, stopped the flow of fluid entirely even after prolonged jugular pressure was applied (fig. 5). If, however, Ringer's solution or hypotonic

saline was given intravenously at the time when drainage ceased, fluid was obtained again in great abundance (fig. 4).

When this small amount of markedly hypertonic solution was introduced into the blood stream, there was an almost instantaneous fall in the specific gravity of the whole blood and serum. A 15 per cent dilution was observed repeatedly. This dilution can be accounted for only by the assumption that the hypertonic solution concentrated the blood sufficiently to draw water in large amounts from the soft tissues into the blood stream.<sup>3</sup> During the period of maximum dilution of the blood, the cerebrospinal drainage increased. As the excess water was

Fig. 5.—Changes in the drainage and specific gravity of the cerebrospinal fluid after the intravenous administration of distilled water and a solution of sodium chloride to a long-haired cur weighing 13 Kg. The line of open circles represents the amount of cerebrospinal fluid drained; the line of solid circles, the specific gravity of the cerebrospinal fluid. The heavy black areas along the lower scale represent, respectively: 90 cc. of distilled water, and 100 cc. of a 15 per cent solution of sodium chloride.

removed from the blood, the cisternal drainage decreased (compare with fig. 1).

3. Kinsman, J. M.; Spurling, R. G., and Jelsma, F.: Blood and Cerebrospinal Fluid Changes After Intravenous Injection of Hypertonic Solutions, *Am. J. Physiol.* 84:165, 1928.

After intravenous injections of hypertonic dextrose and sodium chloride solutions, there was a prompt increase in the specific gravity of the cerebrospinal fluid. The concentration was frequently as high as eleven points in the fourth decimal place (figs. 3, 4 and 5). With the increase in concentration of the fluid, the drainage decreased. At the point at which the fluid almost ceased to drain, the concentration was greater.

Concentration of the fluid was first observed following the intravenous injection of a 50 per cent dextrose solution. Quantitative sugar

Fig. 6.—A comparison between the specific gravity of the cerebrospinal fluid (fig. 4) and that of a solution prepared by mixing with Ringer's solution quantities of dextrose found by analysis to be identical with those contained in the samples of cerebrospinal fluid. A long-haired cur weighing 20.4 Kg. was used for the experiment. The line of open circles represents the cerebrospinal fluid; that of solid circles, the synthetic solution. The heavy black areas on the horizontal scale represent, from left to right: 400 cc. of Ringer's solution, 100 cc. of a 50 per cent solution of dextrose, and 200 cc. of a 0.45 per cent solution of sodium chloride.

analyses of the samples of fluid revealed an increase in the sugar content in five minutes after the injection began. In ten minutes, the sugar content of the fluid had increased from 66.6 mg. to 357 mg. per hundred cubic centimeters.

If the increase in the specific gravity of the fluid was entirely due to the addition of sugar, one should be able, knowing the sugar content of each cerebrospinal sample of fluid, to prepare a solution which would give specific gravity readings identical with those of the fluid samples themselves. Such a series of dextrose solutions was prepared, in which Ringer's solution was used as a solvent. (Ringer's solution has nearly the same specific gravity as the normal cisternal fluid.) The specific gravity readings on the cisternal fluid and the synthetized fluid were almost identical until the injection of dextrose (fig. 6). At this point

Fig. 7.—An x-ray picture of a dog's head. After the intravenous injection of 100 cc. of a 15 per cent solution of sodium chloride, air was drawn through the cisternal needle into the ventricular system spontaneously, thus giving an outline of ventricles in the roentgenogram. The outline of the ventricles was retouched on the original film.

the specific gravity of the cisternal fluid was consistently higher than that of the synthetized mixture. This would indicate another factor than the addition of dextrose to explain this concentration. Presumably the cerebrospinal fluid becomes concentrated not only from the absorption of dextrose but also from the loss of water. When hypertonic sodium chloride was injected into the blood stream, it appeared in the cerebrospinal fluid in the same manner as dextrose.

Another interesting observation was forthcoming from the experiments with hypertonic solutions. In one animal a perfect ventriculogram was produced by giving a 15 per cent sodium chloride solution intravenously in the presence of a freely draining cisterna magna (fig. 7). Soon after the sodium chloride solution was given, the drainage ceased. Prolonged jugular pressure failed to produce fluid. A sound of suction was heard as of air entering the needle. An x-ray picture of the dog's head was made, twenty-five minutes after the saline was given, and the ventricular system was plainly outlined. None of the air could be seen in the subarachnoid space except at the cisterna magna.

The presence of air in the ventricular system may be explained in three ways: 1. There is a continued or possibly increased absorption of fluid through the normal channels, without a comparable production. 2. There is an actual reversal of flow through the choroid plexus (an osmotic effect). 3. The effect of both of these factors may be augmented by shrinking of the brain, a result which is well known to follow hypertonic injections.

#### COMMENT

Dialysis is generally accepted as responsible for the production of cerebrospinal fluid.<sup>4</sup> The experiments under discussion add further weight, possibly, to the evidence that supports this theory.

A balance may be said to exist between the hydrostatic pressure forcing fluid out of the capillaries and the osmotic pressure attracting fluid into the capillaries. By the reduction of the pressure of the cerebrospinal fluid this balance is altered, since the effect of hydrostatic pressure is increased. More fluid escapes from the capillaries, and, as will be seen, the capillaries become increasingly permeable to substances which they ordinarily hold back.

The rapidity of the interchange of water and solids between the blood and cerebrospinal fluid is the most striking feature of these experiments.

The part which continuous drainage plays in these phenomena is as yet imperfectly determined. It is interesting to compare the foregoing observations with those of Fremont-Smith<sup>5</sup> as to the time at which dextrose appears in the cerebrospinal fluid after its intravenous administration. He found that when the subarachnoid system is closed, dextrose does not appear in increased amounts until one or two hours after its intravenous administration. In the present experiments, in the

presence of free drainage, dextrose appears in the fluid in large amounts a few minutes after its introduction into the blood stream.

Sodium chloride apparently passes the barrier of the cerebrospinal fluid with equal facility. Whether drugs with larger molecules than dextrose and sodium chloride contain will pass into the cerebrospinal fluid, in the presence of free drainage, will be the subject of a future communication. It would seem probable from the work done thus far that the permeability of the choroid plexus and the perivascular spaces is increased when there is a freely draining subarachnoid space.

From the clinical point of view, continuous drainage of cerebrospinal fluid with dicephalesis has proved of inestimable value in the treatment for certain infections of organs of the central nervous system.<sup>6</sup> Presumably the beneficial effects are the result of provision for escape of the inflammatory products and continuous lavage of the subarachnoid space by an increased production of fluid.

#### SUMMARY

Experiments were performed on dogs with a freely draining cisterna magna.

Isotonic solutions injected intravenously diluted the blood, increased the drainage and diluted the cerebrospinal fluid.

Hypotonic solutions produced the same general effects as did Ringer's solution. The results of injecting distilled water were somewhat paradoxical.

Hypertonic solutions at first produced dilution of the blood and increased drainage. This effect on the drainage was immediately reversed. The cerebrospinal fluid became concentrated through absorption of the injected substance and loss of water. During the course of one of these experiments, air was drawn into the ventricles spontaneously and a ventriculogram was taken.

Theoretical bearings and clinical applications of these observations are discussed.

# MASTOIDITIS IN ACUTE NUTRITIONAL DISTURBANCE \*

LYMAN RICHARDS

Among the many factors contributing to the present infant mortality, there persists today a symptom-complex, the death rate from which is appallingly high. I refer to the clinical entity known here in Boston as acute nutritional disturbance. It presents the picture of a previously well and happy infant who, often within the space of a week, is precipitated into a most prostrating illness, characterized by fever, diarrhea, vomiting, dehydration and loss of weight. The condition is analogous to the older disorders known as "summer diarrhea," "summer complaint," "cholera infantum" and acute enteritis.

Etiologically, there are three basic disorders responsible for the production of the same clinical group of symptoms: (1) improper feeding, (2) a true enteric infection restricted to the gastro-intestinal tract and (3) a para-enteral infection characterized by a focus outside the gastro-intestinal tract. It is therefore obviously essential to determine which of these three conditions is present before rational therapy can be applied. In this paper I shall deal primarily with the para-enteral group and the relation of the symptoms to the suspected focus of infection.

The location of this focus, depending somewhat on postmortem examination, has been variously placed in the lungs, kidneys or in any other organ that showed evidences of acute infection. Such observations, however, have been of little avail in furthering or improving the treatment for this distressing condition, and pediatricians have continued to rely on the varied therapeutic aids, such as ideal diets, administrations of para-enteral fluid and transfusions.

Suddenly, about three years ago, certain western otologists advanced the hopeful and novel suggestion that the suspected focus of infection might lie in the middle ears and mastoids. This suggestion had its fundamental basis in the discovery that at postmortem examination many of these infants showed purulent secretions in these structures. Forthwith, the most acute attention was devoted to the otoscopic examination of these babies; incision of the drum membrane was carried out when infection of the middle ear was in any way suspected, and gradually enthusiasm extended to the opening of the mastoid antrum in patients who failed to show improvement after simple drainage of the middle ear. Reports of this procedure were encouraging, and the work was gradually taken up in other parts of the country, among them, Boston.

---

\* From the Otolaryngological Department of the Children's Hospital

For the past three years at the Children's Hospital, this work has been pursued hopefully and patiently, perhaps also a little skeptically. The pediatric staff has cooperated closely, and an attempt has been made to hold a broad and balanced view of the condition as a whole.

#### AURAL FEATURES OF ACUTE NUTRITIONAL DISTURBANCES

As a basis of this summary, I have selected reports of 100 cases which were filed under the diagnosis of acute nutritional disturbance, the incidence of aural features being entirely disregarded. I did this with a view to discovering, first, how frequently aural complications occurred in these cases; second, the varied outcome of those which were so complicated and those which were not; and particularly, the results that followed actual surgical treatment for otitis media when present.

In this group of 100 patients, 31 recovered and 69 died, a mortality of 69 per cent. The cases cover an approximate period of two years, with 63 per cent falling within the months of August to November and the rest scattered throughout the year. The average age of the babies was 6½ months, the younger ones showing a somewhat higher rate of death than the older ones.

Of the infants who recovered, there was no evidence in the family history to suggest that the infection was contracted from another child. In the family histories of those who died, there appear no less than four instances in which a twin of the patient either died within a few days or was suffering from the same symptoms, a fact certainly suggestive of some common source of infection.

Statistically, the infants who weighed most at birth and who were fed longest on the breast tended to recover more frequently, and as far as subsequent feeding was concerned, the babies who recovered oftenest had had the least trouble with their formulas and had gained normally.

The onset of illness was essentially sudden in all but a few cases, with an average duration of symptoms before entrance of from six to seven days for all babies, regardless of outcome. This precipitous change from a well baby to a desperately ill one in such a short time was a feature of striking frequency.

#### SYMPTOMS

Regardless of the outcome, the vast majority of the children complained on entrance of diarrhea and vomiting. Sometimes these two complaints were equally distressing; more often, one symptom antedated the other or exceeded it in severity. In addition, there were numerous patients in whom recent loss of weight was noted, and others with convulsions, high fever or loss of appetite. Once started, the vomiting was apt to be severe and not infrequently projectile.

In only three instances was there any initial complaint of otitis media or discharge from the ear. From the parents' point of view, the ears attracted no attention from the gastro-intestinal symptoms.

#### PHYSICAL SIGNS

The outstanding physical signs mentioned in almost all of the records of these babies concerned their external appearance. Again and again one reads the description of extreme prostration, an ashy gray color, sunken eyes, an anxious, restless look, dehydration and all the evidences of an acutely prostrating illness of the gravest degree.

For otologists, interest in this problem centers about the causal relationship of infection of the middle ear to the general condition of nutritional disturbance. The vital question may be put as follows: Is an existing or latent infection of the middle ear the primary inciting cause of these systemic symptoms; is it a contributing factor, at times powerful enough to turn the balance against recovery; or is it simply a secondary complication, resulting from generally lowered resistance and occurring in a locality in which infection is notoriously common in infants?

If it is the inciting cause, nothing is so important as that it be recognized at the earliest possible moment and the patient immediately treated in the hope of warding off the tragic sequelae which are only waiting a chance to follow. If it is contributory, it should again be recognized and the patient treated as soon as possible in order to lighten the load on the already heavily burdened system. If, however, infection of the middle ear is a secondary complication, much like bronchopneumonia or septicemia, one must feel far less enthusiastic about any radical operative procedures in a patient already beyond the aid of the ordinary measures available in this desperate condition.

What, then, was found at the initial otoscopic examination of these babies when they were admitted to the hospital with prostration, dehydration, projectile vomiting, and with from five to fifteen stools a day?

Among the thirty-one patients who recovered there were fourteen with normal drums, fifteen in which one or both drums showed only redness or congestion, and two with redness and bulging. Of the sixty-nine who died, there were twenty-nine with normal drums, twenty with evidence of congestion, seven with redness and bulging and eight with discharge and perforation. These were the original otoscopic signs. Some allowance must be made for their absolute accuracy, as they were made by pediatricians who were naturally not always appreciative of slight deviations from the normal. Nevertheless, in most instances, the data were sufficiently accurate to bear out the fact that in a high percentage of cases, the infection of the middle ear at

the time of entrance had not advanced to the point of evidencing the normal criteria for true infectious otitis media. I am thoroughly aware that other investigators have pointed out the fact that in this disease-complex one does not find the customary generalized redness and bulging that denote the ordinary acute otitis media and that one must rely on less obvious symptoms in suspecting an involvement of the middle ear. Numerous cases which I myself followed with daily otoscopic examinations have convinced me that at the time of entrance to the hospital and in the presence of the most severe systemic symptoms, it was often impossible to establish the existence of a true otitis media which manifested itself only at a later date.

After examination what treatment was employed in the patients who came under the foregoing classification? In the group that recovered, all drums with bulging were incised soon after the patients' admission to the hospital, as were 75 per cent of the drums which showed only congestion.

In view of the outcome, it is natural to interpret the effect of incision of these reddened drums as highly successful. However, another smaller group of patients in the same class, whose ears were not opened, likewise did well. All of these patients meanwhile received the utmost care from the point of view of feeding, clyses and transfusions. Incision of a drum membrane which had an appearance in any way suggestive of infection was simply one added therapeutic measure undertaken in the hope of preventing the dreaded upset in balance between gradual recovery and a fatal issue. Whether the incisions in these reddened, congested drums were necessary, whether in every instance they were of any real value, is open to question. They were made in drums which, judged by the usual standards of otologists, would have been left undisturbed and free to undergo the normal convalescence which one is accustomed to see so often in patients whose only symptoms are referred to the ear.

How, then, are otologists to estimate the indications for, and the value of, incision of the drum in these cases? The fact that some drums reported to be normal on admission were found subsequently to present evidences of infection and to require incision leads one inevitably to the conclusion that everything possible should be done to prevent such a secondary complication, lest the addition of this infection should prove to be the final straw which turns the balance against recovery. If incision of even a suspicious looking drum will achieve this end, it is indicated at the earliest possible moment. If subsequent events, such as entire lack of drainage or a rapid return to the appearance of a normal drum, prove the incision to have been unnecessary, nothing has been lost, though the question still remains as to whether incision of a

congested but bacterially uninfected drum cannot immediately pave the way for an acute infectious otitis media.

Comment should be made on the fact that in only 8 of these 100 patients was any discharge present from an existing acute otitis media. In these 8, it is possible to visualize a severe infection of the middle ear which had previously developed and for some reason occasioned such violent systemic reactions as to precipitate the infant into the acute nutritional disorder. But how can the fact be explained that in 92 others the infection of the middle ear had at most reached only the stage of a bulging drum and, in by far the greater number of instances, had not advanced beyond even the point of congestion of the tympanic membrane? There can be only two possibilities. Either in the latter cases there is no infection in the middle ear or at most a non-infectious congestion, or else subsequent otologic developments are of a secondary nature, dependent on lowered resistance and tending only to contribute to the severity of the systemic disease already present.

#### TREATMENT ON ADMISSION OF PATIENTS WHO DIED LATER

Every drum membrane that showed redness and bulging was incised on admission or soon afterward. In spite of the establishment of good drainage of a purulent exudate, the procedure here failed to prove efficacious. Temperatures refused to drop; vomiting and diarrhea continued in spite of all subsidiary measures; weight fell steadily, and hope of recovery dwindled. Here the otologist is evidently confronted with so severe a toxemia that removing or at least lightening the load contributed by the aural infection is not sufficient to swing the tide in favor of recovery. It is at just this point that the much discussed and recently advocated procedure of mastoidectomy or antrotomy comes up for consideration. To this, I will return shortly.

A word next as to the group of those patients who died whose initial otoscopic examination showed either normal drum membranes or simple redness or congestion of the drum. (Let it be understood that there has been no disregard of the question of a sagging of the canal wall as a criterion of infection in the antrum. This important evidence was carefully considered in all the patients seen in consultation.)

Of the patients with normal or congested drum membranes, exactly half had one or both drums incised either immediately or within from two to fifteen days. The delayed cases were those in which the procedure did not seem indicated at the outset, but in which, owing to the babies' failure to improve on other treatment, it was resorted to as a possible aid. Here, of course, one cannot refute the criticism that some of these patients might have been saved by earlier incision, although there were a substantial number treated by immediate incision of the

drum who nevertheless died like the rest. Drums which appeared equally inflamed were allowed to go untreated in the group of patients who recovered.

In the forty-four patients who had one or both drums opened, either at once or within a few days, there was a mortality of 66 per cent. In the thirty-six who did not have the drums opened, there was a mortality of 60 per cent, a relatively slight difference if one considers the potentialities of infection of the middle ear.

Faced with a patient in whom apparently satisfactory drainage of the middle ear was taking place but who was obviously doing poorly, what more could the otologist do? Secondary incisions of the drum, even the ones in which particular attention was paid to extending the incision up into the superior canal wall toward the outer wall of the antrum, proved wholly ineffective in the cases reported. Thus, one approaches the crux of this matter from an otologic point of view, viz., In what cases is drainage of the mastoid antrum indicated; how soon should it be performed; what, if any, are the classic indications for it, and what results may be expected from it?

Certainly the procedure as carried out in other clinics has been to withhold the mastoid operation until it was definitely seen that simple though thorough incision of the drum was not sufficient. The greatest difficulty has been precisely at this point. If operation is delayed until it is plainly evident that drainage of the middle ear will not suffice and a fatality ensues, one must perforce conclude that operation was withheld too long. Consequently, one decides to be more alert with the next case; the operation is performed at a decidedly early stage, with the result that normal antral cells or cells filled only with apparently congested mucosa are opened. If a fatal issue follows, it is felt that an unnecessary operation was performed which may have been just enough of an additional burden to the child to turn the tide of recovery. Let me cite some of the results, disappointing as they have been.

#### RESULTS OF TREATMENT

In twelve of this series of 100 patients, single or double operations for drainage of the mastoid antrum in acute nutritional disease were performed. In these operations the technic recommended by those whose results have been more successful was employed, all but one being performed under local anesthesia. Three of these patients recovered, and nine died.

Time does not permit a detailed account of the three cases in which recovery occurred, but in all of them the pathologic changes found at operation were so slight as to justify the opinion that the patient would have recovered with simple incision of the drum alone.

The nine fatalities were disappointments from a surgical standpoint. The operations were done in all stages from early to late and showed all the pathologic changes from pale, thickened mucous membrane to frank pus. The patients received the utmost in the way of supportive treatment both preoperatively and postoperatively, so that it was not felt that the mere surgical shock of the operation was a deciding factor. The outstanding impression resulting from these operations always resolved itself primarily into this: the operation, regardless of whether an infected mastoid antrum had been drained or not, did not appear to have improved the patient's general condition to any appreciable extent. The feeling was always borne in on us that the babies were too sick to benefit by having a subsidiary condition remedied. We were forced to the conclusion that if adequate drainage of the middle ear would not suffice, at least temporarily, to break the trend of the illness, then no amount of treatment of the mastoid would do it either.

I feel that these experiences with operations on the mastoid have been somewhat at variance with those of physicians in the Middle West. I can explain this only on the assumption that the acuity of illness of the patients has been greater, the course more precipitate, and the opportunity to carry them along over a greater period of time has been too limited. Reports in which children with acute nutritional disturbance have benefited by operations on the mastoid one or two months after the onset of the illness would scarcely fit the picture of my patients, who lived an average of only five days after operation.

When a baby who is approximately holding his own nutritionally is suddenly beset with an infection of the middle ear and threatened extension to the mastoid, operation may well prove successful. Two thirds of our patients were not holding their own. They were overwhelmingly sick, and the evidences of infection of the middle ear which so many of them showed appeal to me as those of a secondary infection lighting on a defenseless and already overtaxed system, surgical treatment for which may be locally effective but cannot cure, except in such a proportion of patients as can maintain sufficient resistance to overcome the infection. In the majority, I believe that adequate incision of the drum will be every bit as successful as drainage of the mastoid antrum.

Moreover, I am still seeking an explanation for the fact that among a large group of infants who have been treated either in the outpatient clinic or in hospital wards for all degrees of otitis media and mastoiditis, not one has yet shown any secondary symptoms or signs even approaching in severity those of acute nutritional disturbance. I cannot rationalize this fact with the theory that otitis media is the primary focus in these patients.

Autopsies were performed on thirty-four of the sixty-nine patients who died. In fourteen of these thirty-four, examination of the head was not permitted, but there was found throughout the body a great variety of pathologic conditions, too numerous to mention, but capable of assuming overwhelming proportions. Some of them were, to be sure, probably terminal; but the evidence would seem to be in favor of a disease affecting various systems, and it is not unreasonable to believe that the middle ears and mastoids become involved in much the same way as the lungs or heart or kidneys. From this point of view, the otitis media is again the result of secondary invasion, and although it contributes its share toward overwhelming the patient, treatment of it must not be expected to set matters to rights when other and perhaps more serious factors are also at work.

In the group of twenty patients in whom autopsy of the head and hence of the middle ears and mastoid was permitted, three normal middle ears and mastoids, ten infections of the middle ears but not the mastoids and seven infections of the middle ears and mastoids were found. In three of these there had been no incision of the drums, as so few local signs were present to call attention to an aural infection. Nevertheless, mastoiditis was found at autopsy, a fact which might well be interpreted as a failure to treat patients whose condition required urgent surgical intervention. But let it be understood that these changes in the middle ear and in the mastoid did not represent the only post-mortem pathologic processes in these patients whose other organs showed the same range of pathologic conditions that was found in the group with head restrictions. It is almost certain that in the latter group permission for autopsy on the head would have resulted in the discovery of a like proportion of infections of the middle ear and mastoid.

In closing, I wish to submit a concrete group of figures which I feel are the most illuminating feature of this investigation. They were compiled by Dr. Charles MacKham and Dr. Sidney Farber of the Children's Hospital who made and reviewed postmortem examinations of the middle ears and mastoids of 120 infants who died in the hospital. Of this total, 60 died with a clinical diagnosis of acute nutritional disturbance. The remaining 60 covered a wide range of all the other possible diagnoses. Of the 60 who had nutritional disturbances, 21 did not show any abnormality of either the middle ear or the mastoid, while the corresponding figure for the nonnutritional cases was 26, a difference of only 8 per cent. Of the 60 nutritional cases, 39 showed combinations of pus in either one or both middle ears with or without extension into the mastoids. There were 34 instances of infection of the middle ear and mastoid in the nonnutritional group, again a difference of only 9 per cent. In other words, these infections of the middle ear and mastoid discovered post mortem were but a tenth more

prevalent in patients with acute nutritional disturbance than in those dying from a wide range of other diseases. From these figures, it is hard to come to any other conclusion than that infection of the middle ear with or without mastoiditis is, in infants at least, a prevalent complication in a large number of fatal illnesses, and that the opinion that this local aural infection is a factor of peculiar etiologic significance in acute nutritional disease is not borne out by these authentic figures. The primary or secondary nature of such an otitis media may still be a subject for debate. In either case there is no argument as to the value of establishing drainage of the middle ear as early as possible. In favorable cases in which the patients are not too overwhelmingly prostrated, this may be just enough to turn the tide in their favor and to set them on the convalescent course. In the other patients, I can only feel that operations on the mastoid will avail but little if adequate incision of the drum has proved futile.

# PROBLEMS IN NORMAL AND IN ABNORMAL PHYSIOLOGY OF THE GALLBLADDER \*

LESTER R. WHITAKER

Knowledge of the physiology of the gallbladder has taken great strides during recent years, but there is still much about this apparently simple organ that is baffling. It is known that the gallbladder stores and concentrates bile during the intervals of digestion and expels it into the intestines on demand. But the specific stimulus and the mechanism through which the contents of the gallbladder are expelled have not been worked out thoroughly. The mechanism for concentration of bile in the gallbladder through absorption of water seems simple, but other functions of the mucosa through which other materials are absorbed are not understood. Ordinarily during fasting, the gallbladder is distended with concentrated bile which tends to become inspissated if the vesicle fails to empty. During this process, varying amounts of mucus are secreted. Though one may assume that this mucus tends to prevent excessive inspissation or to act as a lubricant to facilitate the expulsion of the concentrated bile during digestion, there is no certain knowledge of its action. Furthermore, the question as to why the function of a gallbladder which has been acting normally becomes so altered as to allow the formation of gallstones remains unsolved.

When the proper stimulus arises, usually as a result of the ingestion of food, the contents of the gallbladder are expelled in varying amounts, over variable periods of time, according to conditions. Bile may leave the gallbladder almost as soon as food leaves the stomach, or its passage may be delayed for an hour or more after feeding; it may be rapidly and continuously expressed until the vesicle is not only empty, but dry; the action may be intermittent, very slight, or absent, especially if the condition of the subject be poor.

Since emptying of the gallbladder is generally associated with feeding, the question arises, which foods afford the most effective stimulus?

In 1923, Boyden<sup>1</sup> discovered that feeding a mixture of egg yolk and cream would produce emptying of the gallbladder of a cat as deter-

mined by inspection at necropsy. Lean meat had less effect, and rice least of all. In 1925, a group of men in the surgical clinic of the Peter Bent Brigham Hospital, working with the new Graham-Cole method of cholecystography, discovered that a meal rich in fat would produce a sudden marked reduction in size of the cholecystogram in man, which apparently resulted from discharge of bile into the intestine. These workers then found that pure fat was most effective, protein much less, and that carbohydrates were apparently ineffective to this end.<sup>2</sup> Further investigation showed that in the cat absolute emptying of the gallbladder could be produced by feeding pure fat,<sup>3</sup> that proteins varied in their action, though it was generally slight, and that carbohydrates were inactive.<sup>4</sup>

There has been much controversy over the question as to whether the passage of bile from the gallbladder is an active function of the musculature of the vesicle itself or whether it results from extrinsic factors; but now it can be said definitely that the contents of the gallbladder are expelled chiefly by the contraction of its own musculature, and for the following reasons:

The wall of the gallbladder contains a large proportion of smooth muscle the function of which, wherever it may be, is contraction. Its contractility in the gallbladder has been repeatedly demonstrated.<sup>5</sup> The question, however, is, can muscular contraction expel the contents of the gallbladder? This has been demonstrated roentgenologically (*a*) by the expulsion of iodized oil after the administration of smooth muscle stimulants such as barium chloride, (*b*) by the evidence of contraction rings in the vesicle during evacuation of its contents, (*c*) by the appearance of spasm in certain parts or the whole organ while it is emptying, (*d*) by the elongation of the gallbladder during emptying and

relaxation during rest<sup>6</sup> (fig. 1), (*e*) by actual measurements showing a marked increase in pressure in the gallbladder after feeding,<sup>7</sup> (*f*) by noting in the exposed viscus contraction after feeding, with changes in shape and reduction in size,<sup>8</sup> and also (*g*) by the observation of peristalsis in the gallbladder of a fish.<sup>9</sup> It is especially significant that, as I have observed, the gallbladder in the cat can be emptied so completely after feeding that it becomes contracted into a hard knot containing no fluid.

One good reason for doubting a passive mechanism for emptying the gallbladder is that an effective active mechanism has been demonstrated.

Fig. 1.—Muscular activity of the gallbladder. *A* shows the resting gallbladder in a cat six hours after injection with iodized oil (trilobed organ). *B* was taken ten minutes after feeding egg yolk. Note the elongation of each lobe of the viscus as the musculature contracts. *C* was taken twenty-five minutes after feeding. The vesicle appears to be in marked tonus. In *D*, taken twenty-four hours later, the musculature has relaxed and each lobe of the gallbladder has reverted to its original shape (Am. J. Physiol. 78: 428 [Oct.] 1928).

and another is that if the gallbladder emptied passively it would be the only hollow viscus in the body containing smooth muscle to function in this manner. However, extrinsic factors as effective expulsive agents can be ruled out for the following reasons: (a) pressure changes within the abdomen due to respiration, etc., have no effect;<sup>10</sup> (b) elimination of the sphincter of the common bile duct by cutting<sup>11</sup> or an inlying tube<sup>12</sup> or cannula<sup>13</sup> produces no emptying by elastic recoil of the viscus or otherwise; (c) intestinal peristalsis has no effect, since food material can be seen by roentgen examination to pass through the whole alimentary tract without change in the gallbladder (fig. 2); and in the fasting animal, with presumably distended gallbladder, physostigmine does not produce any change in the cholecystogram;<sup>11</sup> (d) increased flow of bile from the liver after giving bile salts does not cause the cholecystogram to disappear;<sup>11</sup> (e) the cholecystogram becomes more dense as the vesicle reduces in size after feeding;<sup>14</sup> (f) with all hepatic ducts tied off, preventing any possible washing-out effect of bile from the liver, the gallbladder empties normally and almost completely after feeding.<sup>15</sup>

Having determined that the contents of the gallbladder are expelled by contraction of its musculature, I shall discuss the nature, source and mechanism of the stimulus which initiates and controls this activity.

It has long been held that the action is reflex, the stimulus arising from the presence of food or acid chyme in the duodenum, and traveling over nerves to the gallbladder. This has not been disproved, but the weight of evidence is against it. Food and hydrochloric acid and magnesium sulphate, which is also supposed to act as a reflex stimulant, can often be passed through the duodenum without effect on the gallbladder (fig. 2); the gallbladder can be denervated by cutting all the nerves in the gastrohepatic ligament and sectioning the common bile duct, and yet exhibit normal emptying after feeding (fig. 3).<sup>16</sup>

16. Whitaker (footnote 6, second reference, and footnote 3).

It has been held also that there is a reciprocal nervous mechanism whereby the gallbladder is made to contract when the sphincter of the common bile duct is opened. There is little evidence for this assumption. The chief evidence against it is: Duodenal peristalsis which is supposed to open the sphincter<sup>17</sup> does not induce the gallbladder to contract;<sup>11</sup> increased flow of bile from the liver after giving bile salts, which presumably opens the sphincter, does not cause the gallbladder to contract; after destruction of the sphincter the gallbladder contracts normally during digestion;<sup>11</sup> in two cases I have observed that a gallbladder containing iodized oil would contract and inject the hepatic ducts against

Fig. 2.—Evidence that contraction of the gallbladder does not depend on peristalsis in stomach or duodenum. *A* shows the gallbladder of a cat containing iodized oil. *B* was taken fifteen minutes after feeding iodized oil; the stomach is emptying and there is no change in the gallbladder. In *C*, taken three hours after feeding, the stomach is empty; the oil is passing through small intestine and into colon. Still no change has occurred in the gallbladder. *D* was taken ten hours after feeding highly absorbable fat in the form of egg yolk; the gallbladder is three-fourths empty.

the antagonism of a closed common duct sphincter, little or no oil passing into the duodenum.<sup>17</sup> This occurred once after feeding and once after intravenous injection of olive oil emulsion (fig. 4).

17. Copher, G. H., and Kodama, S.: The Regulation of the Flow of Bile and Pancreatic Juice into the Duodenum, *Arch. Int. Med.* 38: 647 (Nov.) 1926.

Fig. 3.—The illustration shows that the musculature of the gallbladder may contract after feeding without extrinsic nerves. The tissues of the lesser omentum were severed except the hepatic artery and portal vein, which were stripped of outer coats. The bile duct was cut and cannulated. *A* shows the denervated gallbladder containing iodized oil; *B*, the gallbladder ten minutes after feeding olive oil emulsion; and *C*, five hours after feeding oil. The fundus of the gallbladder is apparently in spasm. *D* was taken fifteen hours after feeding. The vesicle is empty, showing only as a shadow form; the cannula is seen above.

Fig. 4.—Lack of reciprocal action between the gallbladder and common duct sphincter is shown. In *A* the resting gallbladder contains iodized oil. There is no oil in the ducts or duodenum. *B* was taken ten minutes after the injection of olive oil emulsion intravenously. The gallbladder has contracted, injecting the hepatic ducts against the resistance of the common duct sphincter; however, the sphincter has not entirely held, a very small amount of oil having passed into the duodenum (right, above).

If the motor stimulus to the gallbladder does not arise through reflex nervous action it would seem that some hormone or substance absorbed from food into the circulating blood would furnish it. With the gallbladder denervated, it is difficult to see how it could be stimulated otherwise.<sup>11</sup>

Ingested fats are extremely active in emptying the gallbladder, while pure proteins have little effect, and carbohydrates none.<sup>4</sup> It is a striking fact that a single intravenous injection of a few cubic centimeters of highly emulsified olive oil or of egg yolk will produce as much emptying of the gallbladder, without apparently otherwise affecting the animal, as the ingestion of a larger quantity of the same material.<sup>10</sup> Nevertheless, it seems unlikely that fat in the circulation is the actual stimulus to motor activity of the gallbladder, and experiments have shown that apparently the gallbladder may empty without increase of fat in the blood.<sup>18</sup>

The passage into the circulation of a secretin-like product developed in the duodenum through the action of food or hydrochloric acid has been suggested as a stimulus to the musculature of the gallbladder.<sup>19</sup> The intravenous injection of a purified fat-free extract of the duodenal mucosa has been found to empty the gallbladder.<sup>20</sup> Also, hydrochloric acid applied to the duodenal mucosa has produced this effect. Even in dogs whose circulation was crossed, the blood of one dog flowing into the vessels of another, the application of hydrochloric acid, tenth normal, to the duodenal mucosa of the one dog caused the gallbladder of the other to contract.<sup>21</sup> These experiments leave little doubt that some substance enters the circulation which stimulates the musculature of the gallbladder. This is more probable since, as previously mentioned, the gallbladder will empty after feeding though denervated.

But, for several reasons, the question still remains as to whether there is a specific hormone produced by the action of hydrochloric acid in the duodenum or otherwise. Highly emulsified fat injected intravenously is as effective in emptying the gallbladder as extract of duodenal mucosa. Also, the gallbladder may empty spontaneously although it usually remains quiescent for days or weeks during fasting (figs. 5 and 6). And the gallbladder may empty after feeding in the presence of a highly alkalized stomach content.<sup>3</sup> Furthermore, it would seem

Fig. 5.—Apparently spontaneous contraction of the gallbladder. *A* shows the resting gallbladder of a cat containing iodized oil. Oil is also in one of the hepatic ducts. *B* demonstrates that there was no change after one and one-half hours. In *C*, taken twenty-two hours later when the animal was fasting, the vesicle is actively contracting. Note the oil in the intestine. The slight degree of emptying indicates that this process has just begun. *D* was taken six hours later; the contraction has stopped. The oil in the intestine has passed into the colon.

Fig. 6.—Showing apparently spontaneous emptying of the gallbladder. *A* shows the resting gallbladder of a cat three hours after injection of iodized oil. There is no oil in the intestine. *B* was taken two hours later when the gallbladder was actively contracting and about seven-eighths empty.

that if the musculature of the gallbladder is normally stimulated by a hormone produced through the action of hydrochloric acid in the duodenum, the stomach would be a necessary factor in such a mechanism. But with the stomach removed, the esophagus being anastomosed with the duodenum, the gallbladder may contract normally after the ingestion of fat (fig. 7).

Thus it would appear that the origin and nature of the normal stimulus which initiates tonic contraction in the musculature of the gallbladder resulting in expulsion of its contents has not yet been determined.

The concentrating function of the gallbladder is of considerable importance. The mucosa is richly supplied with lymphatics and blood

Fig. 7.—Normal contractile activity of the gallbladder after fat feeding, with the stomach absent. *A* shows the resting gallbladder thirty-six hours after removal of the stomach, connecting the esophagus and duodenum, and filling the gallbladder with iodized oil. *B* was taken three hours after feeding 50 cc. of egg yolk and water by tube. The gallbladder is contracting vigorously; the cystic and common ducts are full, with oil in the intestine. In *C*, taken four hours after feeding, the gallbladder is still contracted, but emptying has ceased. From one-third to one-half the contents of the gallbladder have been forced into the intestine. *D* was taken twenty-four hours after feeding. The gallbladder has relaxed, refilled with bile and resumed its original shape. Compare with figure 1.

vessels through which water is absorbed. Numerous estimates have been given as to the extent of the concentrating power.<sup>22</sup> This function, of course, greatly increases the efficiency of the vesicle as a storage

22. Rous, P., and McMaster, P. D.: The Concentrating Activity of the Gallbladder, *J. Exper. Med.* **34**: 47, 1921.

reservoir but, if carried too far, through failure of emptying, overconcentration and precipitation may occur.

Another function of the mucosa is probably significant—that of secretion of mucus. This may be pronounced. If the sphincter of the common bile duct be cut, preventing reflux of bile into the gallbladder, the vesicle will be found after several days to be moderately filled with mucus. The rugae of the mucosa will be swollen as if loaded with it. Varying amounts of mucus are noted in the bile of the gallbladder of apparently normal experimental animals; at times the vesicle contains almost pure mucus, only slightly tinged with bile.

Thus there are at least three distinct normal activities of the gallbladder: (1) expulsion of its contents through muscular contraction, (2) concentration of its contents through absorption of water and (3) secretion of mucus.

The beginning of pathologic conditions in any organ obviously arises with the alteration of normal function to a point where irreversible changes occur. Therefore, the beginning of disease in the gallbladder must be sought in the multitudinous factors which influence the functions mentioned, and in their interrelations.

For example, if the muscular activity of the gallbladder depends on the elaboration of a hormone through the activity of hydrochloric acid in the duodenum, what happens in cases of achlorhydria, or with a Sippy diet? If the ingestion of fat is a strong stimulus to emptying of the gallbladder, why are heavy feeders more liable to gallstones? The answer to the latter question may be that for some reason the stimulus to evacuation of the gallbladder fails, and the normal concentrating activity of the mucosa favors crystallization, precipitation and formation of stone, especially if the bile be loaded with cholesterol from overfeeding. Perhaps this is prevented normally by the formation of mucus. It is possible also that even though the musculature of the vesicle does not contract, the bile may be displaced by the secretion of mucus, a sort of accessory emptying mechanism.

The mucosa of the gallbladder has another function which may be normal or which may border on the abnormal, or which at least may be associated with the beginning of disease in the organ—the absorption of solid or semisolid matter. It has been shown that small particles of dyestuff placed in the lumen of the gallbladder find their way into the lymphatics, and also that the mucosa probably absorbs cholesterol from the bile.<sup>23</sup> The absorptive action may be selective. The extent to which

---

23. Boyd, W.: Studies in Gallbladder Pathology, *Brit. J. Surg.* **10**: 337, 1923; Some Points in the Pathology of the Gallbladder, *Canad. M. A. J.* **17**:1015, 1927. Fowweather, F. S., and Collinson, G. A.: Certain Chemical Changes Associated with Gall-Stones, with Special Reference to the Relation between Gall-Stones and Hypercholesterolaemia, *Brit. J. Surg.* **14**: 583, 1927.

the mucosa may take up fat is illustrated by figures 8, 9, 10 and 11. When iodized oil is placed in the gallbladder of a cat or dog and induced to remain there for several days by fasting the mucosa will be found on inspection to have a markedly whitish appearance, which looks much like cholesterosis<sup>24</sup> in the human gallbladder, both grossly and under reflected light with the binocular microscope. Figures 8 and 10 illustrate this appearance, and figures 9 and 11 show the massive absorption of fat which may take place in the mucosa without definite pathologic change.

Fig. 8.—Appearance of mucosa of cat's gallbladder after absorption of iodized oil, resembling "strawberry" gallbladder of human being. At the top is a gross specimen of gallbladder which had contained iodized oil for several days; below, mucosa under a binocular microscope.

Boyd<sup>25</sup> advanced the theory that cholesterol is absorbed from bile by the mucosa until pedunculated masses are developed in the rugae which finally break off and form the nucleus of cholesterol gallstones (fig. 12). The absorption of such large amounts of fat as shown in the figures tends to support this theory. Boyd also holds that cholesterosis and

24. Mentzer, S. H.: Cholesterosis of the Gallbladder, *Am. J. Pathol.* **1**: 383 (July) 1925.

25. Boyd (footnote 23, first reference).

stone formation result from the deposit of cholesterol from an overloaded bile in a mucosa the function of which is altered by inflammatory reaction. Such a sequence might have occurred in the case illustrated by figures 13, 14 and 15, although inflammatory changes in the wall of the gallbladder were not sufficient to prevent contraction of its muscula-

Fig. 9.—Absorption of fat by the gallbladder of a cat. Iodized oil was kept in the vesicle for several days. The cells of the mucosa are loaded with fat globules and fat is seen in the subserous lymphatics (below).

ture as shown by the cholecystogram (fig. 16). However, if the marked absorption of fat shown in figures 8, 9, 10 and 11 is significant, it would seem that cholesterosis of the mucosa might occur more readily in the normal organ. If that is true it is probable that simple functional stasis

Fig. 10.—Absorption of fat by mucosa of gallbladder of a dog in which iodized oil had been present for several days. (Binocular lens 40 mm.)

Fig. 11.—Stained sections of gallbladder of a dog (same as in fig. 10) after absorption of fat. 1. Cross-section of wall showing no definite reaction except possibly a slight increase of lymphocytes in the stroma of the villi. 2. Fat stain showing globules of fat in epithelial cells and in stroma of villus. 3. Regular stain showing normal structure of cells except for fat vacuoles. There is perhaps a slight increase of lymphocytes in the stroma, but on the whole the tissues are remarkably free from inflammatory reaction. It would seem that absorption of fatlike bodies comes within the range of normal function of the mucosa.

in the gallbladder in the presence of a hypercholesterolized bile could result in gallstone formation.<sup>26</sup> It is conceivable that a person might, through overfeeding, increase the cholesterol content of the bile and at the same time reduce the muscular efficiency of the gallbladder, along with that of the alimentary tract in general, thus inducing gallstone formation. And this might occur simply as a result of perversion of function, without inflammation as a predisposing cause, or even as an

Fig. 12—Gallbladder from a patient showing pedunculated cholesterol masses in the mucosa (arrows). This patient had had typical symptoms of disease of the gallbladder, yet the mucosa was otherwise normal and the wall showed only slight lymphocytic infiltration. It is possible that these masses had been breaking off and producing symptoms.

associated condition Hansen<sup>27</sup> has produced gallstones in rabbits by feeding cholesterol after narrowing the cystic duct

26 Aschoff, L. Lectures on Pathology, New York, Paul B. Hoeber, Inc., 1924.

27. Hansen, S. Die Bedeutung des Cholesterins für die Bildung von Gallensteinen durch experimentelle Untersuchungen beleuchtet, *Acta chir. Scandnav.* 62: 483, 1927.

Fig. 13.—Painting of fresh specimen of human gallbladder containing mixed cholesterol stones, masses of cholesterol crystals, and cholesterosis of the mucosa. Yet the mucosa of this gallbladder was able to concentrate bile and the musculature was able to contract. Microscopically, the mucosa did not stain well, which was perhaps due to cholesterosis. The only evidence of inflammatory change was a slight infiltration of lymphocytes in the wall. It does not seem possible that so meager an inflammatory reaction could have produced such a condition. It would seem that the cholesterosis and not the inflammation was the primary factor in this case.

There are many patients who show a normally functioning gallbladder by cholecystography, i.e., a mucosa which will concentrate the salt used and a musculature which will contract, and yet the vesicle may be the seat of cholesterosis and stone formation (figs. 13, 14, 15, 16, 17 and 18). Furthermore, in these cases the gallbladder may be thin-walled and show only slight evidence of inflammation microscopically. The examples represented by the figures are extremely interesting in this particular.

Fig. 14—Mucosa of gallbladder shown in figure 13. The drawing was made from the fresh specimen under a binocular microscope. Note the varying degrees of cholesterosis

Should the bile contain no excess of cholesterol when stasis occurs, it is possible that increasing concentration may lead to precipitation of other constituents of the bile with the formation of other types of stones,<sup>28</sup> also without marked pathologic alteration of the gallbladder. By simply inducing stasis and hyperconcentration of bile through fasting and dehydration for several days in animals under barbitol anesthesia, small masses resembling gallstones have been produced.<sup>28</sup>

28. Whitaker, L. R.: Biliary Stasis as a Factor in the Production of Gall Stones, *Surg. Gynec. Obst.*, to be published

Fig. 15.—Drawing of crystals found in a drop of bile from the gallbladder shown in figures 13 and 14. Note the large number of cholesterol crystals.

Fig. 16.—Cholecystograms in case represented by figures 13, 14 and 15. In *A*, the shadow of the gallbladder is somewhat fainter than normal due to a diseased mucosa (cholesterosis) or debris in the gallbladder displacing the opaque substance; in *B*, there is a definite contraction after a fat meal due to an active musculature. This is, of course, limited on account of the debris (fig. 13).

The idea of infection as a direct cause of gallstone formation has become almost a fetish. Why assume because bacteria are found inside gallstones that the bacteria are the cause of the gallstones? They may simply be there when the gallstones form. Why assume because inflammatory changes are found associated with gallstones that the inflamma-

Fig. 17.—Human gallbladder showing cholesterosis (below) with formation of a cholesterol stone. The epithelium and muscularis were apparently normal, with only a slight infiltration of lymphocytes and plasma cells in the wall, and there was no fibrosis.

tory changes are primary? It may be the other way. Inflammatory changes do occur without gallstones and gallstones of many varieties are found with very meager functional or structural evidence of inflammation.

Fig. 18.—Cholecystograms in case represented by figure 17. In *A*, there is a shadow of normal density indicating active concentration by the mucosa. Note the notch in the right side corresponding to the transverse ridge at the fundus in figure 17. This is a normal structural variation. *B* shows the disappearance of the shadow one hour after a fat meal, indicating an active musculature. Figures 17 and 18 illustrate that a gallbladder may be the site of slight cholecystitis and cholesterosis with stone formation and yet concentrate and contract, and give a normal cholecystographic response.

Fig. 19.—This illustration shows that debris (ground up gallstones) can be expelled from the gallbladder of the cat without damage to the vesicle. In *A*, the gallbladder contains iodized oil (below) and crushed gallstones (above); in *B*, after fat feeding, the gallbladder is contracting, expelling stones and oil; *C* shows the gross specimen of gallbladder and duets, normal microscopically, after the expulsion of debris.

Yet stones have been produced by the intravenous injection of streptococci resulting in inflammation of the gallbladder.<sup>29</sup> But Wilkie<sup>30</sup> has shown that the wall of the gallbladder is chiefly involved in these experiments and seldom the mucosa. Also, in patients, it has been found that the wall of the gallbladder is more often infected than the bile.<sup>31</sup> Why should gallstones be formed in the bile under these conditions? It seems probable that infection and inflammation of a certain degree in the wall of the gallbladder inhibit the musculature, with induction of stasis, while concentration of the vesicular content goes on

Fig. 20.—Expulsion of debris by the gallbladder of a cat without permanent damage. *A* shows the gallbladder containing ground up gallstones from a patient, and iodized oil; *B*, several days later, after feeding. The oil, and presumably debris, cleared out of the gallbladder. *C*, the gross specimen (taken at once) shows a normal gallbladder, microscopically, containing only concentrated bile.

through a functioning mucosa, favoring precipitation and stone formation.

It is likely that through overeating, or pregnancy, or conditions associated with rapid loss of weight, the cholesterol in the bile is increased; and that stasis in the gallbladder is induced at the same time through functional disturbance or by infection, resulting in cholesterosis with the accumulation of debris in the gallbladder (fig. 13). Conversely, it is possible that the cholesterol in the bile can be decreased by chance or by design, and that the functional disturbance or infection of the gallbladder can be relieved, with return of muscular power; and that then the debris, if not too abundant or in too large masses, may be forced out of the viscus, with a return to normality.

Since the massive amount of oil loading the mucosa in figures 8, 9, 10 and 11 disappears in a few weeks, it seems probable that if abnormal formation of cholesterol in the bile and its absorption by the mucosa should cease the cholesterosis might be relieved eventually, either by vital activity of the mucosal cells or by desquamation and regeneration. Then the debris in the gallbladder, if not in masses too large to pass the ducts, might be expelled by an active musculature. Figures 19 and 20 illustrate the expulsion of ground up gallstones by the gallbladder of the cat, which proved to be normal afterward. It may be that in patients gallstone formation actually begins, but, its causes relieved, the viscus returns to normal. The development of a rational method for prevention of disease in the gallbladder, and an effective method of early treatment depend on the expansion of knowledge concerning the normal and abnormal physiology of that organ.

# GLYCOGENOLYSIS DUE TO EPINEPHRINE IN HEPATIC DISEASE\*

SELLING BRILL

The tests for liver function now available in clinical practice are not by any means satisfactory. Following a suggestion in the brilliant work of Mann and his co-workers,<sup>1</sup> and in line with other known facts of the physiology of the liver, it was thought that a study of blood sugar curves following injections of epinephrine might provide a method of clinical value for testing one of the functions of the liver.

An initial optimism gave place, as the experiments proceeded, to a feeling that this particular test of liver function would doubtless fall short clinically in much the same way that others have, because of the old difficulty inherent in all functional testing of an organ with manifold functions and a tremendous margin of reserve. Nevertheless, the sound physiologic bases of the test to be discussed and certain of the experimental results justify the belief that it may offer something of scientific if not of clinical value.

Blum,<sup>2</sup> in 1901, was apparently the first to point out that the injection of an extract of the suprarenal gland into the experimental animal caused glycosuria. Velich,<sup>3</sup> in 1903, showed that in frogs suprarenal glycosuria did not occur if the liver was removed. Paton<sup>4</sup> and Metzger<sup>5</sup> demonstrated that the glycosuria following the injection of suprarenal extract was the result of hyperglycemia. Subsequent observers

not only confirmed this fact, but found that the hyperglycemia was much more consistent than the glycosuria, and that a fairly characteristic blood sugar curve could be obtained dependent on the dosage of the extract. The source of the increased sugar in the blood was presumed to be the glycogen reserve of the body, chiefly that of the liver. This could not be demonstrated easily because of the difficulty of depleting the supply of glycogen in the animal. Finally, Mann and Magath<sup>6</sup> were able to show that after total hepatectomy in dogs, epinephrine did not have any effect on the progressive hypoglycemia. This was later confirmed by Soskin.<sup>7</sup> Similarly, Collens, Shelling and Byron<sup>8</sup> did not find any effect on the blood sugar level in dogs after injections of epinephrine when the arterial supply to the liver was excluded. These observations indicate that the hyperglycemia caused by epinephrine is dependent on the mobilization of glycogen from the liver. Macleod,<sup>9</sup> in discussing the behavior of glycogen of the muscles after hepatectomy, concluded, "that the muscular glycogen can only be called upon to a very limited extent, if at all, to supply glucose to the blood. It has an entirely different function from the hepatic glycogen which represents surplus stores of condensed carbohydrate." Choi,<sup>10</sup> working in Macleod's laboratory, was recently able to substantiate this view experimentally. His results led him to state that muscle glycogen, in the breaking down process, was not converted into dextrose, but into lactic acid, and that epinephrine did not have a direct effect on muscle glycogen as far as dextrose synthesis was concerned.

Since the hyperglycemia due to epinephrine depends on the mobilization of glycogen from the liver, it seems logical to suppose that the glycemia curve would vary with the quantity of glycogen in the liver. This has been confirmed experimentally by Markowitz,<sup>11</sup> who showed that in rabbits, the livers of which were rendered temporarily glycogen-free, hyperglycemia due to epinephrine did not occur, whereas when the livers were rendered only partially glycogen-free there was a less marked

hyperglycemia of delayed onset. Also, Olmsted and Coulthard<sup>12</sup> from their work concluded, "adrenalin hyperglycemia depends to a considerable extent on the quantity of glycogen in the liver."

There is a good deal of evidence that in disease of the liver the amount of hepatic glycogen is reduced, with a concomitant lowered sugar tolerance. Clinically, the practice of giving patients with severe damage to the liver a solution of dextrose intravenously seems to be beneficial. Steinbrinck<sup>13</sup> reported marked benefit from the infusion of dextrose in both animals and patients who had derangements of the liver from mushroom poisoning. Bodansky<sup>14</sup> observed a hypoglycemia in animals, the livers of which were severely damaged by chloroform, phosphorus or hydrazine. Ravdin<sup>15</sup> found a markedly subnormal glycogen content of the livers of some animals with experimental obstruction of the common duct. Puxeddu<sup>16</sup> noted that in patients with cirrhosis of the liver, the glycemia curve following the ingestion of 100 Gm. of dextrose differed from the normal in that there was first a drop and then a rapid ascent, which was sustained for at least three and one-half hours before it returned to its previous level. Ferguson<sup>17</sup> recently demonstrated a similar lowered sugar tolerance in animals with experimental liver damage.

From the evidence just presented, the physiologic and pharmacologic bases for this test may be summarized as follows:

1. It is a well established fact that epinephrine hydrochloride injected in adequate dosage into the animal organism produces a marked rise in blood sugar with a fairly characteristic curve dependent on the dosage and method of injection.
2. This hyperglycemia induced by epinephrine is due to accelerated and augmented glycogenolysis in the liver.
3. The nonhepatic glycogen stores of the organism, such as muscular glycogen, are not acted on by epinephrine to produce hyperglycemia and apparently do not play a demonstrable part in glycogenolysis induced by epinephrine.

17. Ferguson, L. K., to be published.

4. The degree of the hyperglycemia produced by injections of epinephrine is dependent to a large extent on the quantity of glycogen in the liver.

5. In extensive disease of the liver the quantity of glycogen in the liver is decreased.

#### METHOD

The experiments were planned along the standard lines of the dextrose tolerance test, an injection of epinephrine being substituted in place of the feeding or injection of dextrose. The patients were from the wards of the Hospital of the University of Pennsylvania. They had the usual hospital "house diet"<sup>18</sup> the day preceding the experiment. Breakfast was not allowed on the morning of the experiment, and the patient was kept in bed. The blood in all cases but one was taken by venipuncture. After the specimen of blood sugar was obtained during fasting, epinephrine hydrochloride 1:1,000 was injected into the deltoid muscle. In one case, it was given intravenously. The dose was 5 or 10 minims (0.3 or 0.6 cc) carefully measured in a tuberculin syringe. Subsequent samples of blood were taken at quarter hour or half hour intervals for an hour and a half to two hours. Estimations of the sugar in the blood were made promptly. In most instances these were estimated by the method of Hagedorn<sup>19</sup> and in a few by the method of Folin and Wu.

Dogs were used for the experiments on animals. They were all on a standard diet consisting of dog biscuits and milk. No attempt was made to force them to eat all that was given them. Sex was disregarded. They were of medium size, weighing from 8 to 12 Kg. Experimental obstructive jaundice was produced by division of the common bile duct and any other branches emptying into the duodenum, inversion of the duodenal end and removal of the gallbladder. The anesthesia was either ether or sodium amytal (sodium iso-amyl ethyl barbiturate) intraperitoneally, 50 mg. per kilogram of body weight. The dosage in dogs varied from 5 minims (0.3 cc.) to 2 cc. of epinephrine hydrochloride subcutaneously (abdominal wall) and 5 minims (0.3 cc.) intravenously. Samples of the blood were obtained by venipuncture, and the sugar estimations were made by the method of Hagedorn in all cases.

#### OBSERVATIONS ON PATIENTS

The patients were divided roughly into four clinical groups: (1) normal persons, without any evidence of disease of the liver or bile tract, and without any obvious disturbance of carbohydrate metabolism; (2) patients with borderline cases, without any demonstrable disease of the liver, but with conditions which might presumably influence the liver adversely (for example, alcoholism without clinical cirrhosis, disease of

A. 81:1055 [Sept. 22] 1923) report that the hyperglycemia due to epinephrine may be modified by diet. I do not believe that the slight variations in the hospital "house diet" in my experiments affected the results. In four patients on whom multiple "curves" were made, no appreciable effect was noted from the diet.

19. Hagedorn, H. C., and Jensen, B. N.: *Zur Mikrobestimmung des Blutzuckers mittels Ferricyanid*, Biochem. Ztschr. 135: 46, 1923.

the gallbladder without jaundice, etc.); (3) patients with mild or relatively early hepatic disease (for example, mild cirrheses, postarsphenamine jaundice, etc.), and (4) patients with severe hepatic disease of widespread character (for example, diffuse carcinoma of the liver, marked atrophic cirrhosis or chronic obstructive jaundice with obvious cirrhosis). Thirty-one patients were studied and thirty-seven blood sugar curves made in these cases. The groups were subdivided into those patients who received 5 minims (0.3 cc.) of epinephrine and those who received 10 minims (0.6 cc.).

In chart 1 are presented the blood sugar curves of eight normal persons who received 5 minims (0.3 cc.) of epinephrine into the deltoid

Chart 1.—Blood sugar curves of normal persons following intramuscular injection of 5 minims (0.3 cc.) of epinephrine hydrochloride. In this and the following charts, the time indicates the interval following the injection.

muscle. In chart 2 are the borderline cases, in chart 3 the mild hepatic cases and in chart 4 the severe hepatic cases. Chart 5 contrasts the average composite curves of the normal persons with those of patients having severe hepatic disease.

#### COMMENT

From a study of the charts, it was apparent that the optimum dose of epinephrine had not been found. The fact that a few normal human beings failed to respond with the expected degree of hyperglycemia seemed to indicate that a dosage of 5 minims (0.3 cc.) was too small for my purpose. However, a fair percentage of normal persons and those with borderline and moderate hepatic disease responded to this dosage as

anticipated. Some of the results are significant. The total average rise in the normal group was over 34 per cent of the fasting level, whereas the total average rise in the group with severe hepatic disease was 14 per cent, and whenever there was a rise in the blood sugar level following the administration of epinephrine in these cases, it was distinctly a delayed rise with a type of curve quite different from the normal. This is well shown in chart 5. It is also in agreement with the observation of Markowitz,<sup>11</sup> referred to previously, who noted that in rabbits the livers of which were only partially glycogen-free, hyperglycemia due to epinephrine was less marked and of delayed onset. The character of the

Chart 2.—Blood sugar curves of patients with borderline cases. Dose, 5 minimims (0.3 cc.) intramuscularly.

"normal" curve is well illustrated by the composite curve of normal persons in chart 5. It differs from what was anticipated in that the high level is somewhat less than it would have been had two of the low normal values been excluded.

Since a few normal persons failed to respond with the expected degree of hyperglycemia following the injection of 5 minimims (0.3 cc.) of epinephrine, the pathologic curves on this dosage are open to criticism on the score of inadequate dosage. The intravenous injection of 5 minimims (0.3 cc.) in a human subject produced such unpleasant symptoms that this route was abandoned forthwith.

Chart 3.—Blood sugar curves of patients with mild hepatic cases. Dose, 5 minims (0.3 cc.) of epinephrine hydrochloride intramuscularly.

Chart 4.—Blood sugar curves of patients with severe hepatic cases. Dose, 5 minims (0.3 cc.) of epinephrine intramuscularly.

Chart 5.—The unbroken line is the average composite curve of normal persons; the broken line, the composite curve of patients with severe hepatic cases. Dose, 5 minims (0.3 cc.) of epinephrine hydrochloride intramuscularly.

A series of patients was then studied with the administration of 10 minims of epinephrine intramuscularly. This series consisted of eleven patients: five normal persons and two from each of the other groups. The results of this series were more consistent. In charts 6, 7, 8 and 9

Chart 6.—Blood sugar curves of normal persons. Dose, 10 minims (0.6 cc.) of epinephrine hydrochloride intramuscularly.

The character of the normal curves as plotted in chart 6 differs from that of the curves in chart 1 (patients who received 5 minims [0.3 cc.]) in that the high level shows a greater rise over the blood sugar during fasting (58 per cent as compared to 34 per cent); the high point is reached later, and, with one exception, at the end of one and three-quarters hours, the level of the blood sugar still shows considerable elevation. This can be seen more easily in a comparison of the composite normal curves of charts 5 and 10. On the other hand, the composite average curve of the patients with severe hepatic disease who were given the 10 minim (0.6 cc.) dosage is essentially the same as the corresponding curve of the patients with severe hepatic cases who were given the 5 minim (0.3 cc.) dosage. The total average rise of the group with severe hepatic conditions who received the 10 minim (0.6 cc.) dosage was 12 per cent of the fasting level. In neither the group receiving 5 minims (0.3 cc.) nor that receiving 10 minims (0.6 cc.) was sufficient divergence from the normal group noted in the patients with borderline cases or mild hepatic disease to warrant the belief that this test would be of any value in early or mild hepatic disease.

During the course of these experiments, certain other observations were made. The intramuscular injection of 5 minims (0.3 cc.) of epinephrine hydrochloride rarely caused any symptoms, except occasionally a temporary mild nervousness. The 10 minim (0.6 cc.) dose not infrequently caused a good deal of trembling and nervousness, sometimes lasting as long as an hour, but the symptoms were never alarming. As stated previously, the intravenous injection of 5 minims (0.3 cc.) of epinephrine caused a marked reaction and was discontinued. Blood pressure readings were taken in several instances following the 5 minim (0.3 cc.) dosage. The results were variable. There was usually a rise in the systolic pressure of from 10 to 20 mm. of mercury, but in some cases it actually decreased, in one instance from 130 systolic and 70 diastolic to 94 systolic and 50 diastolic at the end of one-half hour. Three quarters of an hour later it was back to 125 systolic and 70 diastolic.

#### OBSERVATIONS ON ANIMALS

Our next study was on dogs: (1) normal animals, and (2) dogs with experimental obstructive jaundice. Twenty-two blood sugar curves were made on twelve animals, seven of which were later operated on. The results were disappointing. Dogs evidently tolerate much larger doses of epinephrine than human beings. In dogs, 5 or 10 minims (0.3 or 0.6 cc.) of epinephrine hydrochloride injected subcutaneously caused only a minor rise in the blood sugar level. The subcutaneous injection of 2 cc. doses produced a gradual marked rise which, at the end of two

hours, was still over 100 per cent of the fasting level, and did not show any tendency to decline. The subcutaneous injection of 1 cc. doses caused a similar gradual increase in the blood sugar at a lower level. The intravenous injection of 5 minims (0.3 cc.) of epinephrine produced a characteristic curve with an abrupt sharp rise, the peak (average of nine curves 50 per cent rise over the fasting level) being reached within the first ten minutes, following which there was a gradual decline to the fasting level in an hour and forty-five minutes. When the same intravenous dose was given to a dog that had been jaundiced from one to three weeks, an exactly similar blood sugar curve was obtained, excepting that the peak was at a considerably lower level (average of four curves 30 per cent rise over the fasting level). In chart 11 are presented the blood sugar curves of dog 394. The protocol follows:

Chart 11 (dog 394).—The unbroken line is the normal preoperative curve; the broken line, the curve after eight days of complete experimental obstructive jaundice.

#### PROTOCOL OF DOG 394

On Dec. 16, 1927, a male mongrel, weighing 10 Kg., received an injection of 5 minims (0.3 cc.) of epinephrine intravenously in a hind leg after a sample of blood was obtained during fasting. Six samples of the blood were taken at irregular intervals following this. On Dec. 22, 1927, an operation was performed under sodium amytal anesthesia. The common bile duct was doubly ligatured and severed. The distal end was inverted in the duodenum. The cystic duct and vessels were tied and severed and the gallbladder was removed. Closure was made without drainage. On December 28, results of the van den Bergh tests were as follows: direct, immediate; indirect, 7.5 units. On December 30, the results were: indirect, 12 units. On this date another blood sugar curve was made with the same dosage of epinephrine as described previously. On January 6, the dog died. The liver was removed for glycogen extraction and pathologic sections.

## SUMMARY AND CONCLUSIONS

Blood sugar curves in normal persons and in patients with hepatic disease following the injection of epinephrine hydrochloride are presented. The experiments were designed to formulate a test for liver function based on glycogenolysis induced by epinephrine. A marked difference in the character of the blood sugar curve following the intramuscular injection of 10 minims (0.6 cc.) of epinephrine was noted between normal patients and those suffering from severe hepatic disease. Such a uniform distinction was not observed between normal patients and those suffering from mild hepatic disease.

The experiments on dogs were inconclusive.

We do not believe that this test will be of much clinical value unless, perchance, further work reveals that glycogenolysis is one function of the liver which becomes unreservedly impaired in certain forms of disease of the liver before other evidences of hepatic breakdown are so obvious that a test is superfluous.

The clinical implications of this work which seem valid are (1) that patients with marked, widespread, disease of the liver will give after the injection of epinephrine an almost flat blood sugar curve, and (2) that such patients should be given large quantities of dextrose preoperatively and postoperatively.

# HEMOLYTIC STREPTOCOCCAL SUBCUTANEOUS GANGRENE

REPORT OF A CASE \*

JOHN FALLON

Separately, gangrene caused by the streptococcus and infection limited to subcutaneous tissue are well known entities. The combination of the two is not widely understood. This combination, whether or not one chooses to call it a disease, does follow a distinctive course, has predictable possibilities of complication, and is benefited by a particular treatment.

Meleney has written an excellent, and apparently the original, account of hemolytic streptococcal subcutaneous gangrene.<sup>1</sup> The essential lesion is gangrene of the subcutaneous tissue. Secondly, this kills part of the overlying skin, possibly by vascular interference. The subcutaneous lesion is broader than the cutaneous lesion, that is, it undermines. Both are surrounded by cellulitis. Deep tissues are rarely involved unless a preceding wound has penetrated them. Meleney showed that the cause is a hemolytic streptococcus. In nineteen of the cases he reported, there were four deaths.

In Peking, where the condition is not uncommon, Meleney saw about thirty-five cases in four years. It was probably seen but not recognized on the western front<sup>2</sup> during the World War. One case has been reported<sup>2</sup> and six others have been recognized<sup>3</sup> in this country. There seems to be no other mention of it in the last few years, although much has been written of gangrene of the scrotum, which may be but a discriminative localization of it, and something of "necrotizing erysipelas"<sup>4</sup>—a half-brother.

*A priori*, such a condition should not be confined to China. Rather, one might infer that the diagnosis is missed in this country. Examination of about 750 case histories of peripheral infections and gangrenes at the Peter Bent Brigham Hospital, the Mayo Clinic and the Saint

Vincent (Worcester) Hospital has revealed a half-dozen cases suggestively similar to that here reported—if retrospect diagnosis may be so far honored.

#### REPORT OF CASE

*History.*—A robust Irish-born multipara, aged 32, entered the Peter Bent Brigham Hospital, Sept. 17, 1925, complaining of tenderness in the right breast. Though the nipples were cracked, she had been nursing an infant, aged 2 months. About a week before entry, she noticed a little tenderness and pain in the right axilla and had two chills. She did not remember any other discomforts except an occasional feeling of feverishness until the day before entry. Then tenderness, swelling and redness appeared in the right breast, and the infant refused to nurse.

Despite a temperature of 104 F. and a leukocyte count of 16,000, the patient did not appear ill. On the outer part of the right breast was a lesion best described as a circle-within-a-circle. First there was a dull red central area, 8 cm.

Fig. 1.—Appearance of breast on sixth day of disease. Shown chiefly for orientation but illustrates imperfectly three stages of the condition: at *A* is the outer red-brown zone; at *B* the blebs, and at *C* the “pigskin” appearance of skin covering an area of subcutaneous gangrene; this stage precedes the skin slough. Active slough appears at *D* and completed slough at *E*.

in diameter, moderately indurated and edematous, with raised border, and only moderately tender, and then a few centimeters of peripheral zone composed merely of dull brown-redness. Enlarged axillary nodes or other relevant signs were not found.

**Third Day:** The following day, the temperature and general condition were the same. The inner zone of induration had spread; its margin was more cleancut, and its surface showed blebs and “pigskin appearance” (intracutaneous edema).

**Fourth Day:** The outer zone involved the whole breast, and much of the inner zone was black; the blackness appeared suddenly and was sharply demarcated.

**Fifth Day:** The temperature was normal; for the first time, the patient looked really ill. The outer zone had spread, and much of it had become edematous. The skin over the area that was black on the fourth day was now pearly-white

and dead-looking. This suggested ischemia, and that the blackness on the previous day had been due, not to sudden gangrene of the skin, but to hemorrhage beneath it.

Sixth Day: The central area, which had been black, then white, was black again and sloughing (figs. 1, 2 and 3). There had been no fluctuation, and enlarged nodes did not appear until three weeks later.

Fig. 2.—Appearance of breast on sixth day. If this figure and figure 3 showed the streptococci, they would illustrate all the "cardinal signs" of the condition after the slough has appeared. They show: gangrene; rapid advance (the slough *A* was one day's progress); undermining (i. e., the primary involvement of subcutaneous tissue); and secondary involvement of skin (necrotic border, *B*). The amount of undermining on the sixth day was about the same as that shown by the hemostat on the eighteenth day.

Fig. 3.—Appearance of breast on eighteenth day.

Ninth Day: The local lesion looked better, but the patient was very ill. Erysipelas appeared over the whole right side of the chest, *posteriorly*, and the next day had involved the upper half of the back; the following day it spread around to the left breast.

Thirteenth Day: When the patient seemed to be dying, she suddenly began to improve, and the following day the erysipelas began to fade. During the next week the temperature did not rise above 101 F., and the lesion started to heal.

Twenty-First Day: The temperature rose, and a subcutaneous abscess of the left breast was opened; it had been only slightly red and tender. There was still an occasional chill, and the temperature rose every day to 103 or even 104 F. for almost a month.

After the seventh week the fever was slight, and by the tenth week the skin defect was filled. Toward the end a small, painless pus-pocket just beside the original lesion had flared up; but throughout the course of the fever repeated examinations and roentgenograms of the chest had failed to show any other secondary localization. The patient was discharged on the eighty-ninth day, when there had been no rise of temperature for eleven days. She was watched for more than two years, and sequelae other than the scar and urinary condition, which will be described later, were not found.

*Clinical Pathologic Changes.*—The early blebs showed staphylococci and gram-negative diplococci. After the sloughing, when the active, undermining parts could be reached, they consistently showed a very hemolytic streptococcus, although

Fig. 4.—Appearance on forty-first day, illustrating healing; adhesion of undermined flaps, contraction of the denuded area, granulating base, and epithelium advancing from edges.

sparse colonies of staphylococci could still be grown from the other parts of the lesion. Anaerobes were not found. Blood cultures gave no growth.

For six months the urine contained rare hyaline and granular casts, slight traces of albumin, and red and white cells, usually in large numbers. During the patient's last two months in the hospital the specific gravity did not rise above 1.012, and phenolsulphonphthalein tests during the same period returned 25 and 30 per cent (two hours and ten minutes after intramuscular injection). Later, the urine cleared, the blood pressure never rose (usually being 125 systolic, 85 diastolic; or less), and, although the patient complained of edema of the ankles, it was never found.

The highest leukocyte count was 19,300; it was usually between 10,000 and 16,000. The erythrocyte count fell from 3,800,000 to 2,700,000; the hemoglobin varied from 60 to 55 per cent (Tallqvist). The Wassermann reaction was negative.

Unfortunately, biopsy of the primary lesion was not made. Biopsy of the area of erysipelas showed only the changes usual to erysipelas.

## COMMENT

*Pathology.*—Meleney did not find characteristic microscopic changes. This case adds nothing to his gross pathologic observations except the suggestion that massive subcutaneous hematoma may cause the skin necrosis seen in my patient on the fifth day of the illness. Unfor-

Fig. 5.—Appearance on sixty-sixth day. The epithelial covering was complete except at *A*. Yet four days later a lateral pocket—like distant abscess and erysipelas, a common complication—appeared at *B*.

Fig. 6.—Appearance of breast at fifteenth month. The scar is the only effect remaining

tunately, the slough finally separated in such an amorphous mass that it could not be determined whether hematoma underlay it. Nor was it proved that the hemolytic streptococcus was the cause. Meleney, however, has satisfactorily demonstrated this.

*Diagnosis.*—This seems to be the only case in which the early appearances have been reported. The process was at once too superficial and too widespread to be an abscess and, unlike erysipelas, the redness and edema were dissociated. Cellulitis was more difficult of exclusion, and the exclusion was possible not because of this or that, but because of the composite: the two zones; the intracutaneous edema and its limitation to the inner zone; the speed of march; the cyclic color changes; the lack of fluctuation and of adenitis; the discrepancy on the one hand between the angry looking lesion and its slight tenderness, and on the other between the high temperature and the apparent well-being of the patient.

Once the gangrene has appeared, the diagnosis may be much more decisive. A number of cases have been seen at this stage, and the phenomena have been constant. Many names are given to infectious gangrenes of the skin, as sphaceloderma, pemphigus gangrenosus and ecthyma; but after the streptococcus has been found, these may be disregarded for something more concrete. The more chronic forms of skin necrosis, blastomycosis, amebiasis cutis,<sup>5</sup> the symbiotic phenomenon of Brewer and Meleney,<sup>6</sup> etc., are ruled out by bacteriologic study and, even in the most rapid cases, their duration. In Pfanner's cases of "necrotizing erysipelas,"<sup>4</sup> the erysipelas preceded the gangrene—not a very essential difference. The "war gangrenes" of bacterial, especially anaerobic, origin do not show subcutaneous localization. They do not leave flaps of undermined skin comparatively uninvolved, and peel fat and connective tissue off the underlying fascia or muscle so as to remind one of the "cleaning" of a careless dissector. And they can be bacteriologically differentiated. However, in the interpretation of bacteriologic studies one should remember that other organisms often accompany the streptococcus in streptococcal gangrene; while the case reported here illustrates the necessity of not being content with the lesser cocci but of searching for the streptococcus repeatedly and in the proper location, that is, in the advancing edge of the undermining.

This streptococcal gangrene is so blatantly infectious that it would never be confused with gangrene of vascular, nervous, or similar origin. In this particular case, the location and the appearance, suggesting massive hemorrhage, suggested apoplexy of the breast,<sup>7</sup> but the process too patently began as an infection.

7. Cutler, E. C.: Apoplexy of the Breast, *J. A. M. A.* **82**:1763 (May 31) 1924.

Practically speaking, a differential diagnosis is academic. I do not believe that any other condition would show gangrene, rapid advance, primary limitation to subcutaneous tissue and hemolytic streptococci. Because of its all-inclusive name, cellulitis offers a theoretical difficulty. One can conceive of chance combinations mimicking the subcutaneous selectivity and the rest of the syndrome, but their treatment should be the same. The isolation of the organism from a clinically typical case may present a real difficulty.

*Complications.*—Secondary localization is the rule, either as a lateral pocket of the original lesion, as occurred on the seventieth day in the case reported, or as an abscess at a distance from the lesion, as was found on the twenty-first day. The abscesses are often multiple, and the organism usually selects the subcutaneous tissue. These abscesses are often painless and lack redness, so, lest they be overlooked, a careful search is necessary with every rise of temperature. Again, Meleney has noted all this. Some of his cases showed, as did the case reported here, a lack of general reaction at first, and most of them the later prostration. Most of them lacked adenopathy, and in none was lymphangitis present. In three, erysipelas occurred. In the case reported here, the crisis may be interpreted as part of the erysipelas rather than of the streptococcal gangrene. Eight of Meleney's cases showed small amounts of albumin. The renal condition in my case is more probably the usual result of toxemia, the so-called nephrosis, than true nephritis.<sup>8</sup> Phlebitis, involvement of the intermuscular septums, osteomyelitis with deep abscess, pyopneumothorax and bronchopneumonia have also been seen as complications. Even without any such setbacks, convalescence is characteristically slow.

*Treatment.*—Meleney made "incisions . . . from the gangrenous area proximally and distally as far as the subcutaneous necrosis extends, but no farther," followed immediately by hot soaking for the cellulitis, and careful daily evacuation of all necrotic material. The last is important, and should be done carefully enough to preserve patent vessels which may pass through the slough to the skin above. It is also time-consuming, if fibrous threads hold the slough in a tough honeycomb. The incisions should not be so close together as to destroy the blood supply of the alternating skin strips. One may be duped to inaction; the subcutaneous lesion usually advances rapidly for from four to seven days and then is often self-limited. Seeing the patient at this time, one might easily believe that the cutaneous slough, too, would not go farther. Meleney tentatively advised amputation if there were early

8. Dr. James P. O'Hare, of the Peter Bent Brigham Hospital, has reviewed the patient's record and given this opinion.

involvement of the bone. Neither Meleney nor I used commercial anti-streptococcal serums, but in 1929, they deserve a trial.

In the case reported, because a diagnosis was not made until after the skin slough, treatment was limited to hot packing and daily toilet of the wound, and later institution of the Carrell-Dakin regimen. Difficult as an affirmative diagnosis would be before the slough appears, one might have a strong suspicion of the nature of the condition. In this case, if it had even been recognized that the process under the skin was far graver than the appearance of the skin, the absence of fluctuation and the deceptive well-being of the patient indicated, it might have been possible to arrive at a diagnosis by an exploratory incision. Then, before the skin itself had become gangrenous, multiple incisions and removal of the subcutaneous lesion might have saved the patient a close approach to death. This is necessarily conjectural, because no patient appears to have been treated so early. It is chiefly to urge the trial of such treatment that this case is reported.

#### SUMMARY

1. Hemolytic streptococcal subcutaneous gangrene is apparently a recognized entity in China, and has been reported once before in the Occident. As there is nothing in its nature to suggest geographic limitation, it is possible that in this country the diagnosis may be missed.

2. The disease or condition is a grave gangrene, which progresses rapidly, is confined primarily to subcutaneous tissue (undermining) and secondarily involves the skin.

3. Sometimes erysipelas and often secondary localization, especially in subcutaneous tissue, are complications.

4. The present treatment is multiple incisions, careful daily toilet of the wound and hot soaking.

5. This paper urges treatment before the slough has involved the skin, describes the early appearance in one case, and suggests exploratory incision as a diagnostic measure. Serums should be tried.

# THE ABILITY TO LOCALIZE SOUND

## A STUDY OF BINAURAL HEARING IN PATIENTS WITH TUMOR OF THE BRAIN \*

THEODORE C. GREENE

### I. THE NATURE OF BINAURAL HEARING

Binocular vision gives a perception of distance through the coördination in the brain of sensations coming from the two retinas and the two sets of ocular muscles. In a somewhat comparable way, one determines whether a sound comes from the right or left side by the coordination of sensations coming from the ears. In other words, the lateral localization of sound <sup>1</sup> is a result of binaural hearing.

A clear understanding of two terms is essential for following a discussion of the subject, and these terms will be briefly explained. In figure 1, *D* represents the head of a listener seen from above. *R* and *L* are his right and left ears. *B* is the position of a sound. The segments of concentric circles represent sound waves.

The listener, *D*, knows that the sound is on his right side, for two reasons. In the first place, the sound is louder in his right ear. In the second place, each sound wave arrives first in the right ear and later in the left ear. These facts may be stated in a different way by saying that the right and left ears are at the same instant being stimulated by different intensities of sound and by different parts or phases of the advancing sound waves. These two factors which enable one to localize sound will be called the intensity factor and the time factor. In some of the literature, the term phase difference is applied to the time factor.

### II. LITERATURE

The earlier work done by physicists favored the intensity ratio as the more important factor in binaural hearing,<sup>2</sup> but Lord Rayleigh <sup>3</sup> in 1907 and Bowlker <sup>4</sup> in 1908 brought out the importance of phase differences. Wilson and Myers <sup>5</sup> concluded that phase differences produced differences of intensity in the ears by cross-conduction through the head.

---

\* From the Surgical Clinic of the Peter Bent Brigham Hospital.

1. The vertical localization of sound will not be treated in this paper, and in what follows "localization of sound" will always be understood to refer to localization in the lateral plane.

5. Wilson, H. A., and Myers, C. S.: The Influence of Binaural Phase Differences on the Localizations of Sounds, Brit. J. Psychol. **2**:363, 1908.

Hartley,<sup>6</sup> however, concluded that the localization of pure tones depends on the direct perception of phase differences. Later, with Fry, he<sup>7</sup> stated that both factors, intensity and time, are necessary. Halverson<sup>8</sup> found much variation of intensity necessary to produce a shift of tones and concluded that phase differences were more important than the intensity factor.

Stewart's work on this subject demands special attention. In 1913, he<sup>9</sup> stated that the intensity factor is important when the observer can turn his head. In 1918, with Hovda, he<sup>10</sup> reported the following significant observations: If one listens to a sound 477 cm. away and 45

Fig. 1.—B, source of sound. D, head of listener seen from above. L, R, his left and right ears. The dotted lines represent sound waves.

degrees to the right of the midline, 20 per cent more sound will reach the right ear than will reach the left ear (if the head is considered as a sphere). Accordingly, if sound is led to each ear by a tube, and if the

10. Stewart, G. W., and Hovda, O.: *Psych. Rev.* 25:242, 1918.

intensity factor alone operated in the localization of sound, it should be necessary to make the sound only 20 per cent louder in the right ear to give the sensation of a sound 45 degrees to the right. Actually it is necessary to make the sound ten times louder in the right ear to produce this sensation. This shows how important is the other factor, the factor of time. In 1920, Stewart<sup>11</sup> stated that the time factor is effective from 100 to 1,200 vibrations a second with 1,000 to 1,500 vibrations a second as the upper limit in localizing pure tones, that the time factor is the more important factor in localizing sound and that it is a phenomenon independent of bone-conduction.

In a review<sup>12</sup> of the subject, it is stated that the angular displacement of the sound is proportional to the phase difference and to the logarithm of the intensity ratio.

One point is familiar to all observers, to Hartley,<sup>6</sup> Hornbostel,<sup>13</sup> and others; it is much easier to localize a noise than a tone. This would seem natural, for in the complex sound wave of a noise each little irregularity in the sound wave offers an opportunity for the time factor to operate. The simple sound wave of a tone does not offer the same opportunity. A very high note<sup>11</sup> or the shrill, piercing chirp of a cricket is difficult to localize.

### III. EXAMPLES OF SOUND LOCALIZATION

Dr. Neven-Spence<sup>14</sup> described a method of route surveying which he used while combating sleeping sickness in Africa. In visiting settlements of natives in bush country in which it was impossible to see far ahead, he had to keep track of his route. The surprising accuracy of Dr. Neven-Spence's system of land navigation depended on his ability to take a bearing with a prismatic compass on the call of a native who traveled one fifth of a mile behind. In this way, the ability to localize sound took the place of the surveyor's rod and theodolite.

A ship with a pair of electrical receivers under water can localize sound. With such an apparatus, which depends entirely on the time factor in localizing sound, submarines can determine accurately the direction of ships invisible to them.

Of more practical value is the everyday help which this sense gives. To the blind this sense must be a special help, and it would be interesting to compare their ability to localize sound with that of normal subjects.

11. Stewart, G. W.: The Function of Intensity and Phase in the Binaural Location of Pure Tones, *Physiol. Rev.* **15**:425, 1920.

12. Bulletin of the National Research Council, Nov. 4, 1922, part 5, no. 23.

13. Hornbostel, E. M., and Wertheimer, M.: Ueber die Wahrnehmung der Schallrichtung, *Sitzungsberichte der preussischen Akademie der Wissenschaften*, 1920, p. 388.

14. Neven-Spence, B.: Route Traversing in Bush Country. *Geog. J.* **69**:143, 1927.

Animals in the field, whose survival depends on alertness and rapid flight in the right direction from attacking animals, must have this sense well developed. The same might be said of pedestrians crossing a street on which there is heavy traffic.

#### IV. THE PROBLEM

Sound localization is a definite sense which is constantly giving useful and accurate information. This sense has been studied in healthy subjects by physicists and psychologists, but a clinical study in subjects with various forms of intracranial disease may possibly bring out a few points. What is the effect of disease of the middle ear, of increased intracranial pressure, of tumors in various lobes of the brain, of a section through the temporal lobe—what is the effect of these conditions on the ability

Fig. 2—"Short-circuited" binaural stethoscope used in preliminary studies

to localize sound? These conditions present an unvalued opportunity in the physiologic laboratory for studying the sense of localization of sound. The operating room becomes the proper laboratory for the problem.

To give all the technical details of the test, to give completely the responses of each patient to the tests, and to discuss all the possible hypotheses would make but weary and confusing reading. This paper is in the nature of a summary of work done during the years 1923, 1924 and 1925, and details which are not reported are at the disposal of any one who is interested in this subject.

#### V. PRELIMINARY STUDIES

A simple instrument may be constructed by "short-circuiting" a stethoscope with a piece of rubber tubing to which a scale has been attached (fig. 2). If the ear-tips are placed in the ears and the rubber

tubing is stroked with some object, such as a pencil or throat-stick, a noise is heard. The position from which the noise seems to come, of course, depends on where the tubing is stroked. The question then naturally arises: How far from the midline must the tube be stroked so that the subject of the test will know that the source of the sound is on one side and not in the middle?

In answer to this question, nine controls, eight otologic patients and fifteen neurologic patients were tested with the "short-circuited" stethoscope in the manner mentioned. Their ability to localize a ticking watch which was moved about the head was also tested, and the relative acuteness of hearing of the ears was tested with a watch.

*A. Otologic Group.*<sup>15</sup>—These patients, all of whom suffered from unilateral or bilateral chronic secretory otitis media, gave repeated examples of excellent localization of sound in spite of marked inequality in the acuteness of hearing of the ears. The average ratio of the shortest distances at which a watch was heard on the two sides was 8:1. This means that the average ratio of the intensities of the sounds required to stimulate the ear in which hearing was less acute and the ear in which hearing was more acute was 64:1. And yet the average displacement of the "middle zone" (the region in which sound seemed to the patients to be in the middle) was only 2.6 cm. from the midline.

*B. Neurologic Group.*—The significant discovery with the "short-circuited" stethoscope in this group was the definite impairment in five patients of the ability to localize sound in spite of apparently normal hearing. With these patients it was necessary to move a sound farther from the midline on either side than was necessary with the controls, or otologic patients, before they realized that the sound was on one side and not in the middle. Two of these five patients had a glioma in the temporal lobe; the conditions found on operation were suggestive of a glioma in the posterior temporal region in the third patient; the fourth patient refused operation, and the fifth had a glioma of the corpus callosum. Lesions in the temporal lobe among the remaining ten patients were two in number.

## VI. DEVELOPMENT OF APPARATUS

The first step in an effort to produce better apparatus was the reproduction of that used by Wilson and Myers for testing phase effects. With this apparatus, which involves a system of tubes, it is possible to produce a sound nearer to one ear and yet have it sound nearer to the other ear. This striking phenomenon is dependent on the time factor.

---

15. The writer is indebted to the staff of the Massachusetts Charitable Eye and Ear Infirmary for permission to study these patients.

In modifying this apparatus for clinical work, it was found that the slide part of a trombone enables one to alter conveniently the length of the column of air which transmits the sound to one ear. This enables one by means of the time factor to cause the sound to shift from one side to the other, as heard by the subject of the test.

I found it impossible to vary the intensity of a sound satisfactorily by passing it through an aperture the size of which was varied. A sound dissipates fairly gradually through a slit in a tube as the slit is uncovered, but a potentiometer proved to be a more satisfactory instrument.

#### VII. APPARATUS USED IN THE TESTS <sup>16</sup>

*A. For the Determination of the Acuteness of Hearing.*—The 2-A audiometer, made by the Western Electric Company, produces a pure tone of varying intensity for each octave from 64 to 8,192 vibrations per second. With the aid of this instrument, a curve may be drawn for each ear showing the threshold of hearing over a wide range of pitch.

*B. A Test for the Ability to Localize Sound Under Normal Conditions of Hearing.*—The patient rested his chin on a support, grasped a steering wheel in front of him and closed his eyes. Turning the steering wheel caused a buzzing sound to move about his head in a semicircle at a distance of approximately a foot. By turning the steering wheel, the patient endeavored to place the sound directly in front of him, in the middle, and the accuracy of his attempt was read on a scale of degrees. (A watch from which the escapement has been removed furnishes a continuous and satisfactory buzzing noise for this purpose.)

*C. Apparatus for the Separate Testing of the Use of the Time and Intensity Factors in the Localization of Sound.*—With this apparatus, the patient hears a sound which shifts from one side to the other. Either the patient or the doctor can cause the sound to shift. The sound can be shifted in two ways. The relative times of arrival of the sound in the ears can be varied, while the intensity of the sound remains unaltered and equal in the right and left ears. Or the sound may arrive simultaneously in the right and left ears throughout the test, while the relative intensity of the sound reaching the ears is varied.

(1) Source of Sound: An old graphophone was contributed by a music store. The point of the graphophone rests in a continuous groove cut in the cylindric record. A noise is much more accurately localized than a tone and the continuous, low pitched, steady, grinding noise thus produced was used with all the patients. With some patients, a pure tone from the audiometer was also used, but this did not prove nearly as satisfactory as a noise.

(2) Path Followed by Sound: An ordinary telephone transmitter is placed in front of the graphophone diaphragm. An electric current, furnished by a dry cell, flows through the transmitter and through the two telephone receivers (R).

16. The Western Electric Company and the Submarine Signal Corporation generously lent apparatus for this work. The writer wishes to express his appreciation to them. In the absence of the compensator made by the latter company the "short-circuited" binaural stethoscope might prove fairly satisfactory, for this simple instrument would seem to use the time factor almost entirely in localizing sound, especially if longer tubing is used. The compensator, however, has many advantages.

and  $R_2$ ) in the compensator. The sound made by the graphophone is thus carried to the receivers in the compensator. A column of air carries the sound from the left receiver ( $R_1$ ) to the left tube of the stethoscope and to the left ear. In like manner, a column of air carries the sound from the right receiver ( $R_2$ ) to the right tube of the stethoscope and to the right ear.

(3) Manner in Which the Relative Intensity of Sound in the Ears is Varied: As indicated in figure 3, resistance is placed across the electrical circuit. A movable contact on this resistance coil leads from a point between the receivers.

Fig. 3.—Apparatus used in testing the ability to localize sound. The graphophone is the source of the sound.  $R_1$  and  $R_2$  represent telephone receivers placed within the compensator. Electric wiring connects transmitter, receivers, battery and potentiometer. The relative intensity of sound going to the ears is varied by the potentiometer. The relative times of arrival of sound in the ears are varied by turning the wheel ( $W$ ) of the compensator. The subject of the test hears sound with the binaural stethoscope.

Moving the contact to the right, for instance, decreases the intensity of sound in the right receiver. The sound arrives simultaneously in both ears throughout this procedure. Unfortunately, moving the contact causes much extraneous noise which should be eliminated in future work. Possibly distilled water could be used for resistance.

(4) Manner in Which the Relative Times of Arrival of Sound in the Ears Are Varied: The excellent transmission of sound by water suggested the problem of localizing sound under water. It was found that the "Compensator" made by the Submarine Signal Corporation, Boston, is an ideal instrument for varying the relative times of arrival of the sound in the ears. It will be remembered that a column of air extends from the left receiver ( $R_1$ ) to the left tube of the stethoscope and that a column of air extends from the right receiver ( $R_2$ ) to the right tube of the stethoscope. When the wheel on the top of the compensator is turned in one direction, the left column of air is shortened, the right column of air is lengthened, the sound waves arrive earlier in the left ear than they do in the right ear, and the sound as heard by the patient shifts to the left. When the wheel is turned in the opposite direction the reverse occurs, and the sound shifts to the right as heard by the patient. The intensity of sound remains equal in both ears. A scale of degrees is attached for determining the position of the wheel. There are no extraneous sounds connected with the shift.

*D. Apparatus for Testing the Ability to Detect Small Differences in Intensity and in Pitch.*—Because it was thought that there might possibly be some relation between the intensity factor in localizing sound and the ability to detect small differences in intensity, an apparatus was devised to test such ability. This merely involved introducing a gradually increasing resistance twice a second into the circuit of the audiometer.

Similarly, because it was thought there might possibly be some relation between the time factor in localizing sound and the ability to detect small differences in pitch (which is a matter of time-appreciation),<sup>17</sup> apparatus was devised to test such ability. A whistle was supplied with air at a constant pressure and the pitch varied by increasing small amounts twice a second by a piston which was connected with a lever. (An electrical system with condensers would be more satisfactory.)

### VIII. ROUTINE TECHNIC OF THE TESTS

An otoscopic examination was made of all patients. If wax was present, this was removed and the tests were performed on a later day.

The acuteness of hearing in both ears was tested with the audiometer or with a watch. In a number of cases, the ability of each ear to detect small differences of pitch and intensity was also tested.

The ability to localize sound was tested under natural conditions of hearing in which the time and intensity factors are simultaneously utilized.

The ability to localize sound was then tested with the apparatus already described which differentiates the time and intensity factors and which permits a separate testing of the use of these two factors in localizing sound. Noise from the graphophone was used, and the patient was asked to turn the wheel of the compensator until the sound seemed to him to be in the middle. The position of the wheel was read on the scale of degrees. *This tests the ability of the patient to use the time factor in localizing a sound.* The noise from the graphophone was then

17. An appreciation of pitch depends on the appreciation of the time interval between successive vibrations.

brought simultaneously to the ears, but the examiner varied the relative intensity of sound coming to the ears by means of the potentiometer. The patient was asked to tell where the sound seemed to be or to point a pencil in the apparent direction of the sound. *This tests the ability of the patient to use the intensity factor in localizing a sound.*

As would be expected, repeated trials were necessary to obtain reliable results. Because an hour was usually required to complete the tests, in the case of all children and several adults half of the tests were done on one day and half on the following day.

#### IX. RESULTS OBTAINED

*A. The Control Group.*—Ten subjects were tested as controls. A larger number would have been desirable. However, so many of the otologic and neurologic patients gave responses as accurate as those considered "normal" that the criteria used in classifying responses were probably not too exacting. Children as young as 9 years of age coöperated excellently in the tests.

The zone in which sound seemed to most "normal" subjects to be in the middle varied in width from a few to 20 degrees (up to 10 degrees to either side of the midline) both in the test for localizing sound under natural conditions and in the test in which a noise was localized with the time factor alone. A width of 20 degrees was taken as a rough dividing line between normal and abnormal responses. It is important to realize that these figures represent the first attempts of subjects to localize sound under such circumstances and are not the responses of a few persons after months of practice in a psychological laboratory. In these studies, the important point is to provide similar conditions for all subjects tested.

*B. The Otologic Group.*—Seven cases of otologic interest were found. Two of these also belonged to the neurologic group. These cases included otosclerosis, perforations of the ear-drum, chronic secretory otitis media and an acoustic neuroma, and many of the patients naturally were partially deaf in one or in both ears. As would be expected, the "middle zone" (in which sound seemed to the patient to be in the middle) was in some cases shifted toward the ear in which hearing was less acute, but in several cases this shifting did not occur. Otherwise the tests revealed essentially normal responses. Disease of the middle ear seems to impair only slightly the ability to localize sound.

*C. The Neurologic Group.*—Fifty-seven patients of the neurologic service at the Peter Bent Brigham Hospital were examined with these tests. Lack of coöperation made the results of no value in six cases, which left fifty-one cases worthy of study.

(1) *The Ability to Localize Sound under Normal Conditions of Hearing:* In this introductory test, the patient endeavored to place a noise in the midline, with his eyes closed, by turning a steering wheel. (The noise was a buzzing watch, moved by the steering wheel.)

In only three patients of the fifty-one who were tested in this manner was the sense of localization impaired. Operation disclosed a large hemangio-endothelioma of the right temporal lobe in one patient; a large glioma in the left parieto-occipital region was found at operation in another patient, and one patient was suspected of having a tumor.

Of the forty-eight patients with a normal ability to localize sound as tested in this manner, fifteen revealed an impaired ability to localize sound when the time factor or the intensity factor was used alone to localize sound. In ten of these fifteen cases the localization of sound was impaired in only one of these factors, but in the remaining five cases the ability to localize sound was shown to be impaired, both in the test which uses the time factor alone and in the test which uses the intensity factor alone. And yet these five patients could localize sound normally when the two factors, time and intensity, were used simultaneously under normal conditions of hearing. This shows the remarkable way in which the brain uses what is left of a damaged sense to effect the normal localization of sound. These observations also show that the ability to localize sound cannot be completely studied by moving a sound about the patient's head and asking him to localize it. The use of the time and intensity factors in sound localization should also be tested separately.

(2) *The Ability to Localize Sound with the Separate Use of the Time and Intensity Factors:* (a) The intensity of sound which arrived in each ear remained equal and unaltered while the sound (as heard by the subject) was shifted by varying the relative times of arrival of the sound in the ears. The ability to localize sound was tested under these conditions in which the time factor alone was used for localization.

(b) The times of arrival of the sound in each ear remained equal and unaltered, while the sound (as heard by the subject) was shifted by varying the relative intensity of the sound which reached the right and left ears. The ability to localize sound was tested under these conditions, in which the intensity factor alone was used for localization.

The responses of thirty-four patients were within normal limits. Abnormalities were detected in seventeen patients (tables 1 and 2).

As shown in the tables, the various positions of the lesions in the thirty-four patients with a normal ability to localize sound demonstrates that this sense is not easily destroyed or impaired. The lesions in the seventeen patients with an impaired ability to localize sound are not confined to any one region of the brain. However, there are two observations of possible significance.

(a) Lesions affecting the temporal lobe are found proportionately more often in the group with an impaired ability to localize sound than in the group with a normal ability to localize sound.

(b) There was choking of the disks in twelve of the thirty-four patients with a normal sense of sound localization and in eight of the seventeen patients with an impaired sense. Among the thirty-four patients with a normal sense, increased intracranial tension was found at operation in ten cases; it was reported absent in three cases; no mention of it was made in thirteen cases, and eight cases did not come

TABLE 1.—Data in Thirty-Four Cases in Which the Ability to Localize Sound Was Normal

Surgical Number	Diagnosis
24243	Glioma: temporal, left
23599	Meningioma: temporal, right (medial part)
24539	Perithelioma: temporo-frontal, left

to operation. Among the seventeen patients with an impaired sense, increased intracranial tension was found at operation in ten cases, no mention was made of it in four cases, and three cases did not come to operation.

Because increased intracranial tension was more common in cases showing tumor of the temporal lobe than in other types of cases in this series, it may be that only one of these two observations is significant and that the other merely follows. With the small number of cases involved, it is difficult to arrive at a conclusion. The distribution of cases showing a lesion of the temporal lobe seems to be the more important, but tension also seems to have some independent effect in impairing the ability to localize sound.

One patient responded normally to all tests before operation, which involved an incision through the right temporal lobe into the lateral ventricle from which a calcified endothelioma of the choroid plexus was removed. Three weeks after operation, the tests were repeated. The ability to localize sound was normal with all tests, but with all tests was less acute than before operation. Unfortunately, there are no controls for this observation.

TABLE 2.—*Data in Seventeen Cases in Which the Ability to Localize Sound Was Impaired\**

Number Surgical		Ability to Localize Sound	
		When the Time Factor Was Used Alone†	When the Intensity Factor Was Used Alone†
23216	Hemangio-endothelioma: temporal, right.....	Completely absent	Markedly impaired
24793	Glioma: temporal, right.....	Markedly impaired	Not tested
24777	Glioma: temporal, right....	Impaired	Moderately impaired
24303	Glioma: temporal, left.....	Normal	Moderately impaired
21347	Chronic cerebral abscess: temporal, left....	Slightly impaired	Normal
23609	Cystic ependymoma: parietotemporal, left..	Impaired	Normal
25616	Meningioma: sphenoidal ridge, right.....	Impaired	Normal
23473	Hematoma: over left cerebral hemisphere.....	Normal	Impaired
24006	Cystic glioma: postcentral, right.....	Impaired	Normal
23917	Glioma: frontal, right.....	Impaired	Slightly impaired
24449	Meningioma: parasagittal, left.....	Slightly impaired	Slightly impaired
23586	Glioma: cerebellar, right.....	Impaired	Normal
23481	Glioma: cerebellar, midline.....	Completely absent	Normal
23390	Medulloblastoma: cerebellar .....	Impaired	Impaired
21340	Glioma: cerebellar, right, unverified. ....	Moderately impaired	Normal
23816	Cerebral metastatic carcinoma.....	Impaired	Impaired
23797	Epilepsy, psychoneurosis .....	Slightly impaired	Normal

\* In this table and in table 1, all diagnoses are operative diagnoses except in nos. 24599, 24920, 24926, 23540, 23526, 23816 and 23797. In nos. 23320, 24588, 24627 and 25616 the diagnosis was also made at autopsy. Nos. 24243, 24540, 21395, 24883, 24573 of the normal cases and nos. 24303 and 24777 of the abnormal cases were tested from nine days to three weeks postoperative. In three cases an operation had been performed at a previous entry. No. 23584 was tested before and after operation. In all other cases, the tests were performed only before operation. The following order indicates the sense in which the following terms are used: normal, slightly impaired, moderately impaired, impaired, markedly impaired, completely absent. In no. 23573 (normal group) the conditions found at operation suggested a tumor in the anterior part of the temporal lobe.

† An explanation of these terms and of the tests is given in the opening paragraphs of this paper, the section on the apparatus used, and the section on the technique used in the tests.

(3) The Ability to Detect Small Difference in Pitch and Intensity of Sound: Twenty-eight and twenty-six patients, respectively, were tested. Abnormal responses were obtained in five and eight cases, respectively. These tests suggest that the temporal lobe more than other parts of the brain is concerned with the ability to detect small differences in pitch and intensity. There seems to be a relation between the ability to detect small differences of intensity and the intensity factor in sound-

localization, which is shown by the impairment of this ability and this factor in the same cases. There also is a tendency for the ear with the greater impairment of the ability to detect small differences of intensity to be on the opposite side from the lesion. But the number of cases is too few for drawing definite conclusions.

#### X. THE LOCATION IN THE BRAIN OF A CENTER FOR THE ABILITY TO LOCALIZE SOUND

The excellent ability of patients to localize sound in spite of marked disease of the middle ear (and labyrinthitis in one case) suggests that the ability to localize sound is situated in the brain. Before it is possible to consider in what part of the brain it is situated, it is necessary to draw some conclusions about the auditory pathways. On leaving the ear, auditory nerve impulses might pass entirely to the temporal lobe on the same side or entirely to the temporal lobe on the opposite side, or impulses may travel from one ear to both temporal lobes. A study of the hearing in the persons with tumor of the temporal lobe in this series favors the conclusion that auditory pathways extend from each ear to both temporal lobes and form a decussation similar to that in the optic chiasm.

Believing, then, that each temporal lobe receives impulses from both ears, one need not go outside the temporal lobe in order to find for the ability to localize sound a situation which will satisfy the one obvious requirement. This requirement is that such a region of the brain must receive auditory impulses from both ears for comparison and coördination. From purely *a priori* reasoning, the temporal lobes would seem the logical location in the brain for the sense of sound-localization. The independent, clinical evidence of the tests reported in this paper also favors some part of the temporal lobes as the most probable region of the brain for a center which enables one to localize sound, with probably one center in each temporal lobe.<sup>18</sup>

Possibly there is only one center, and the side on which this one center is situated depends on whether the patient is right-handed or left-handed. In case there are two centers, the picture may be complicated by nerve tracts connecting the two centers, perhaps crossing in the corpus callosum.

---

18. The tables suggest that lesions in the right temporal lobe are related to the more definite impairments of the ability to localize sound with the time factor. However, the small number of cases makes such a statement a speculation. The assumption that a center for the ability to localize sound is situated in a restricted part of one or both temporal lobes would explain some of the conflicting data reported. A tumor in the temporal lobe, but not in this restricted part, would naturally not impair the ability to localize sound.

## XI. THE RELATIVE IMPORTANCE OF THE TIME AND INTENSITY FACTORS IN THE LOCALIZATION OF SOUND

In the course of these tests, fourteen neurologic patients were found with impairment of hearing on one side. The average ratio for the acuteness of hearing on the two sides in these fourteen patients was 20:1. On the basis of Stewart's calculations, the "middle zone" (in which sound seemed to the patient to be in the middle) should be displaced far from the midline in these patients, if the intensity factor alone operated in localizing sound.<sup>10</sup> (Only 20 per cent more sound reaching one ear should cause a sound shift of 45 degrees, if the intensity factor alone operated.) Actually the displacement was little, if any, in four cases; in six cases, the zone was displaced approximately 8 degrees toward the side with impaired hearing, and in four cases the zone was shifted 8 degrees toward the side with the better hearing. It is obvious that some other factor besides the intensity factor must be operating. As long as the brain can receive some auditory impulses from both ears, even if one ear is much less acute in hearing than the other, there is no theoretical reason why the time factor should not localize sound satisfactorily. Given a patient with impaired hearing in one ear and yet the ability to localize sound almost normally (and such is frequently the case), this ability to localize sound can be explained on the assumption that the time factor is the more important factor in the localization of sound and cannot be explained on the assumption that the intensity factor is the more important.

It has been the experience of previous workers that under normal conditions of hearing, a noise is more easily localized than a tone. In these studies, when the time factor alone was used to localize sound, a noise was much more accurately localized than a pure tone. When the intensity factor alone was used to localize sound, a tone was localized as accurately if not more accurately than a noise. Thus, the results obtained when the time factor alone was used coincided with those obtained under the conditions of normal hearing. Opposite results were obtained when the intensity factor alone was used. The localization of sound under normal conditions has thus more in common with the time factor than with the intensity factor. It would seem that the time factor is the essential, more important factor in the localization of sound.

## XII. SUGGESTIONS FOR FURTHER WORK

1. The concentration required of the patient in localizing sound is tiring. I suggest using only one or two tests with a series of patients and repeating these tests with each patient at several half-hour sessions before operation instead of performing several tests at one session. Probably the localizing test which uses the time factor and a noise gives

the most definite readings and the most significant information. Conclusions of value might be drawn from studying in this way a series of from 100 to 200 patients with tumor of the brain, including 50 patients with a tumor in the temporal lobe. Among other points some relation might be noticed between the nature of the lesion, whether infiltrative or not, and the degree of impairment of the ability to localize sound. It would be advisable for one conducting such work to see personally the exact location of each tumor as it is disclosed at operation. It would be interesting to repeat the tests in several cases after operation. One should record whether the patients were right-handed or left-handed, for this may be of some importance.

2. With the apparatus used in these tests, it is possible to cause the sound to shift toward the left (as heard by the patient) by altering the ratio of intensity of sound reaching the ears, and then to cause the sound to return to the middle by altering the relative times of arrival of the sound arriving in the ears. In other words, the intensity factor can shift the sound in one direction and while the intensity factor continues to act, the time factor, acting in the opposite direction, can bring the sound back to the middle. By a number of such measures of the amount of one factor needed to balance the other factor, it would be possible to draw a curve of the time factor plotted against the intensity factor. The position and shape of such a curve might have some diagnostic value.

3. A patient who was unable to localize a noise with the time factor had a marked degree of hydrocephalus. This recalled the thinning of the corpus callosum which is seen in hydrocephalus and suggested that fibers in the corpus callosum which connect the temporal lobes might be concerned with the localization of sound.

4. It is possible that Guden's commissure, in close relation to the pituitary body, may play a part in connecting the auditory centers, and in this way it may have some relation with the localization of sound. If so, a pituitary tumor might possibly affect the ability to localize sound.

5. In testing a patient for his ability to localize sound, if the hearing is impaired on one side, one expects to see a shifting toward the ear with the less acute hearing of the zone in which the sound seems to the patient to be in the middle. However, in nine cases this shifting was toward the ear with the better hearing, contrary to what one would expect. There is a tendency for this shift to be away from the side with the lesion.

6. It is conceivable that when a sound is made in a patient's ear the electrical potential of the cerebral cortex to which the auditory impulses travel is made by these impulses higher or lower than the electrical

potential of other parts of the cerebral cortex. Accordingly, I made preparations for an effort to lead to an electrocardiograph a current from the temporal cortex while a noise was made in the patient's ear during an "osteoplastic flap" performed under local anesthesia. Time was lacking to make the trial, but it is hoped that someone else will develop this method. Ether would break the synapses, and procaine would probably be unsatisfactory with lower animals because of muscle action currents. This method should be applicable to the study of other senses.

### XIII. SUMMARY

1. The ability to localize sound in the lateral plane is a definite sense which is constantly giving accurate and useful information.
2. If a subject hears a sound on the right side, for instance, he knows that the sound is on the right side for two reasons: (a) Each sound wave reaches the right ear before it reaches the left ear. (b) The sound is louder in the right ear. These two factors in the localization of sound may be called the time and intensity factors. Clinical evidence favors the time factor as the more important.
3. In this paper, a study of the ability of ninety-eight subjects to localize sound is reported. Of these subjects nineteen were controls, thirteen were otologic patients, and sixty-six were neurologic patients. Among the neurologic patients, the diagnosis of tumor of the brain was verified in forty-two cases and was the probable diagnosis in fourteen other cases.
4. The localization of sound under natural conditions is effected by the simultaneous use of the time and intensity factors which were mentioned previously. Apparatus was devised with which the use of these factors in localizing sound was tested separately. The apparatus demonstrated definite impairments in the ability to localize sound which were not detected by the test for sound localization under the usual conditions of hearing in which the subject could use the time and intensity factors simultaneously.
5. Most patients with disease of the middle ear, who were tested, localize sound with almost normal accuracy.
6. There is no constant relation between an impaired ability to localize sound and tumors in any one part of the brain.
7. However, tumors of the temporal lobe are found proportionately more often among patients with an impaired ability to localize sound than among patients with a normal ability to localize sound. Choking of the disks and increased intracranial tension as found at operation are more common in the group with an impaired ability to localize sound than in the group with a normal ability to localize sound.

8. Suggestions for further work are made. Incidentally, a method for localizing functions in the brain is suggested in which an electrical current from the cerebral cortex would be used. Such a current would be caused by a difference of potential produced by nerve impulses reaching the cortex.

#### CONCLUSIONS

There are two possible interpretations of the observations reported in this paper:

1. Lesions of the temporal lobe tend to impair the ability to localize sound.

2. Increased intracranial pressure tends to impair the ability to localize sound. (Special localizing tests are necessary to demonstrate these impairments.)

Although it is possible that one of these two hypotheses is sufficient to interpret the observations reported, both hypotheses are probably true. However, I wish to emphasize the tentative nature of these hypotheses.

Further work along these lines may cause some of the silent areas of the brain to speak.

# THE UNIVERSITY OF WISCONSIN MEDICAL SCHOOL

## A RETROSPECT

BURTON CLARK, JR.

Only a few days ago the new Medical School Building of the University of Wisconsin was opened for classes. This occasion marked the final step in a project begun long ago to found a complete course in medicine at Madison. It, therefore, seems a fitting time to look backward to the antecedents of the present school and see what foundations it has been built on.

One has only to go through the buildings of the new school and hospital to realize how well it is equipped for teaching and for research. The medical unit consists of the Service Memorial Institutes Building just completed; the Wisconsin General Hospital, first opened in 1925, and two smaller buildings, the Bradley Memorial Hospital and the Student Infirmary. All these buildings are of similar architecture and situated between University Avenue and Linden Drive. This medical unit links two other scientific departments of the university, for on one side are the Chemistry and Physics Buildings and on the other side is the College of Agriculture.

To the casual visitor in Madison it must undoubtedly appear as if the medical school there has sprung up over night. Not much more than a year ago, the University of Wisconsin conferred to a small class its first degrees of Doctor of Medicine. Already Madison is recognized as a medical center, having one of the best medical schools in the country. The rapidity with which the school has changed from a struggling group working with inadequate equipment into one in which are found the best of laboratory facilities, abundant clinical material and a large faculty is astonishing. This change is the more astonishing when one realizes that the first slow step to create a medical school took almost seventy-five years, whereas the medical school as it is known today has been largely created in a little more than five.

Since I was a student in the medical science course at Madison a few years ago, this change is of much interest to me. It has prompted me to look further back to the beginning of the idea of medical teaching at the University of Wisconsin, and see by what slow process of evolution it has developed. Looking back over these eighty years of halting progress, one is impressed by the fact that the present school is simply the culmination of a series of steps, carefully planned and held to doggedly against widespread criticism and difficulties by two or three guiding spirits in the university.

The history of the medical school at Madison begins with the year 1848, for in that year a department of medicine in connection with the university was provided for by an act of the state legislature. In older sections of the country, 1848 is, perhaps, not so long ago, but for Wisconsin that year means the beginning of things. It is interesting to note what the situation was at that time.

In 1836, the Wisconsin territory, boasting a population of 11,000, was organized, but in the next decade there was a marked emigration to this territory, so that by 1850 the population had increased about 1,000 per cent. In 1838, only two years after its birth, the Wisconsin territorial legislature passed a bill for the establishment "at or near Madison, the seat of government, of a University for the purpose of educating youth." The bill was approved by Governor Dodge, but, except for the selection of lands, the proposed university was not furthered for ten years.

In 1848, the Wisconsin Territory was organized as a state. The same year, the Board of Regents of the university held its first meeting and elected the first university professor. Early in the following year, this first professor, John W. Sterling, enrolled the first class, composed of seventeen members, in quarters temporarily provided by the citizens of Madison. The original charter of the university drawn up at this time provided for the "erection of four departments: (1) The Department of Science, Literature, and the Liberal Arts; (2) The Department of Law; (3) The Department of Medicine; and (4) The Department of Theory and Practice of Elementary Instruction." Thus, in the same year, 1848, when a department of medicine in connection with the university was provided for by the legislature, the Wisconsin Territory became a state, and the university was definitely organized. The university, its department of medicine, and the state, therefore, are coeval. However, although it was provided for so early, little even resembling a medical school developed until long afterward.

The next thing that one hears of medical instruction is in 1855 when the regents appointed a faculty of medicine and provided for seven chairs of instruction. The university catalog of the following year gave the following members of the faculty of the department of medicine: Alfred L. Castleman, dean, theory and practice of medicine; Ezra S. Carr, chemistry and pharmacology; D. C. Ayres, obstetrics and diseases of women and children; George D. Wilbur, materia medica and botany; Samuel W. Thayer, Anatomy; Joseph Hobbins, surgery; Alexander Schue, instructor of medicine and pathological anatomy, and J. M. Lewis, demonstrator of anatomy. However, as funds for salaries or equipment were not provided, classes were never held, and nothing developed.

Fig 1.—South Hall, one of the oldest buildings on the campus. Some of the early classes in medical science were held here

Fig. 2—Science Hall. Here the botany and zoology classes of the '90's were held, and it later became the home of the medical science course.

Fig. 3.—The Wisconsin General Hospital, which has made possible the institution of the full medical course in connection with the university at Madison.

Fig. 4.—The Service Memorial Institutes Building as it appears from Charter Street. The latest addition to the University of Wisconsin Medical School.

Then, after a lapse of twenty years, the subject was brought up again. In 1875, the legislature transferred to the regents of the university the custody of the Soldiers' Orphans' Home, then situated on Lake Monona about two miles east of the university. The regents were authorized to establish there a medical college. After consulting with the state medical society as to the feasibility of such a project, the regents concluded that the organization of such a college at that time was impractical. Then they asked the legislature's consent to dispose of the Soldiers' Orphans' Home property and to turn the proceeds into needed buildings on the campus with the understanding that a medical college in connection with the university should be organized as soon as circumstances beyond the control of the board warranted the undertaking. At this time, President Bascom stated that such a medical college should be established not in Madison, but in Milwaukee where there were much greater advantages in amount and diversity of clinical material. He added that a medical college in Milwaukee might well be united to the university. At any rate, the legislature authorized the sale of the Soldiers' Orphans' Home, and for many years more the regents did not see their way toward the establishment of such a school.

The reason for these repeated futile attempts to establish a medical college is found in the situation in which the university found itself during its early years. At that time, there was widespread, hostile criticism throughout the state of the way the university was being developed. The public wanted a "real and practical University," while the one which they were supporting had been from its inception almost wholly a classic college. Popular demand for professional schools at the university was strong. However, such schools, and particularly medical schools, were costly—prohibitively so to a university as poor as Wisconsin was at that time. Such a thing as a medical college was out of the question, but something had to be done to satisfy public demand. It was through periodic gestures to organize a medical school that an attempt was made to appease this popular sentiment.

Finally, when nearly forty years had elapsed from the time the medical college was authorized by the legislature, medical training at the university was definitely begun by Dr. E. A. Birge. In 1880, Dr. Birge, who only recently had come to the university as a young man from Harvard, obtained a leave of absence for a year of European study in the medical schools at Leipzig under Dr. Ludwig. He did this in order to fit himself to teach some of the basic medical sciences and to begin the work of organizing the premedical course at the university. Dr. Birge returned to Madison with this purpose in mind, and, sponsored and developed by him, the premedical course grew until it became the more complete medical science course given in 1907. This premedical course was established at the university in 1886. Its object was to give

a preliminary training to students intending to study medicine. Prior to 1907, graduation from this course entitled the student to one year's credit on his medical course at Rush Medical College in Chicago. To this college, most Wisconsin students went.

The medical school at the University of Wisconsin seems rightfully to have had its origin in these early classes in biology given by Dr. Birge. It is true, however, that instruction in some of the sciences preparatory to medical study were given at the university prior to this time. Apparently the first classes in any of the medical sciences were those taught by Dr. David Boswell Reid from 1859 to 1861 in physiology and hygiene, and the classes in comparative anatomy and entomology in 1869 to 1870. Teaching in physics and chemistry was begun in 1878 and 1879 by John E. Davies, M.D., and W. W. Daniels, M.S., respectively. During the first few years, the premedical course included instruction only in inorganic chemistry under Davies, organic chemistry under Homer W. Hillyer, physics under Daniels, biology under Birge and botany under Dr. C. R. Barnes. A few years later, it gained two young men who were to become widely known for their ability as teachers and their contributions to science.

The first of these men, Dr. William S. Miller, came to Wisconsin in 1891 as an instructor in biology. The following year, he began the teaching of histology, embryology and vertebrate anatomy. Dr. Miller has become internationally known as an authority on the structure of the lung, and he is also a great teacher. Together with Dr. Birge, he has given inspiration to a long list of students, some of whom have themselves become well known as teachers of medicine. The other man was Harry L. Russell, Ph.D., who began his work at the university as Fellow in Biology, and who, in 1893, became assistant professor in bacteriology.

It is this modest premedical course, begun by Dr. Birge in 1886, which entitled its graduates to one year's credit in medicine at Rush Medical College which was the first real step in the foundation of the present medical school. Although it was small and had little in the way of laboratories, it soon acquired the reputation of being one of the best schools of its kind in the country, counting among its graduates a long succession of men who have since distinguished themselves as physicians and teachers. Lack of space curtails an appropriate list, but a few names such as the following are, perhaps, representative: Dr. John M. Dodson, Dr. H. B. Favill, Dr. A. J. Ochsner, Dr. J. C. Bloodgood, Dr. G. LeRoy Hunner, Dr. Charles H. Bunting, Dr. E. P. Carlton, Dr. J. D. Madison, Dr. A. W. Meyer, Dr. A. H. Curtis, Dr. H. F. Helmholtz, Dr. J. G. Heuer, Dr. John L. Yates and E. H. Schorer. All these men began their medical education in the premedical course at Wisconsin in the years before 1904.

In 1906, agitation for a college of medicine was again started, this time by the faculty of the premedical course. The renewal of this subject brought forth much active discussion both within the university and outside. The arguments against such a move were the same as had been used against it in all the previous attempts. It was felt by many that a four year medical school situated at Madison would be excessively costly for both plant and carrying charges. Moreover, it could not hope to be a success in view of the lack of clinical material in a relatively small city. It was also argued that, if a medical school were needed, it might much better be placed in Milwaukee, but that there was no necessity even for that, as the needs of medical education of the Middle West were already well provided for by established schools in Chicago and other large cities.

Those in favor of the plan stated that the medical school would offer only the first two years of the course which did not require clinical material nor much expense, since the buildings, instructional force and equipment of the university generally would be adequate. Students taking such a two year course could go elsewhere for their clinical work, and receive credit for the two years' work in medical science which they had had at Madison. This they would be unable to do unless a medical school were incorporated at the university. The shrewd objectors foresaw and feared that the establishment of the first two years of medicine would be followed later by an attempt to establish an entire four year school.

After considerable discussion, however, the Board of Regents at a meeting in December, 1906, decided to ask the state legislature to authorize the first two years of the medical course at the university. This authorization was obtained. The long desired medical school was established the following spring. In the fall of 1907, the first classes in the medical science course were begun. In 1908, the complete second year was begun by the addition of the departments of pathology, medical bacteriology, pharmacology and toxicology. Dr. Charles R. Bardeen came to Madison to teach anatomy and embryology, and to take charge of the development of the new school as its dean. He brought other young men to Madison to develop new departments. Most of these men have remained to find hopes realized in the splendid laboratories of the Service Memorial Institutes Building into which the school has just moved. How well these men were chosen for their ability as teachers and investigators was amply demonstrated in the enviable reputation Wisconsin gained for its two year course. Its graduates have for years been welcomed to advanced standing in all the better schools of the country, so far as the resources of these schools have permitted. As in the days of the premedical course, a large number of the graduates of this course have gone to Rush Medical

College in Chicago, but each year many of its students have also gone to the third year of the medical schools of Harvard, Pennsylvania, Cornell, Northwestern, Illinois and Washington Universities and the College of Physicians and Surgeons in New York.

In its early years, the medical science course was housed in temporary, crowded quarters in buildings belonging to other departments of the university. The department of medicine occupied attics and basements of South Hall, the Chemical Engineering Building and Science Hall. Fortunately, in 1913, the departments of zoology and botany were removed to the new Biology Building, and, in 1917, the department of physics was removed to Sterling Hall, so that considerable room was left in Science Hall. The departments of pathology and medical bacteriology were then removed from the attic of South Hall, and the departments of physiology, physiological chemistry and pharmacology were transferred from the Chemical Engineering Building. Consequently, since 1917, Science Hall has housed all the departments of the medical sciences, together with the department of geology. Since that time, the course in the first two years in medicine has become firmly established.

In 1907, the state laboratory of hygiene was created. This is the laboratory of the state board of health, but it is supported through the university budget and comes within the jurisdiction of the medical school. The state laboratory was placed in South Hall on the university campus in order that advantage might be taken of facilities for research. It has always cooperated closely with the medical school. This laboratory, under the direction of Dr. W. D. Stovall, does an immense amount of routine diagnostic work, such as examinations of throat smears, sputum, blood cultures and water specimens for physicians throughout the state. It is also active in scientific investigation. The laboratory of hygiene has now been transferred to quarters in the new Medical School Building adjacent to the hospital.

In 1915, a somewhat similar laboratory was created by the establishment, by the State Board of Control, of the State Psychiatric Institute across the Lake at Mendota, Wis. Like the state laboratory of hygiene, this institute has a trifold purpose: namely, to carry on scientific research, to teach and to render public service. This laboratory under the direction of Dr. W. F. Lorenz, has rendered invaluable service to the state in giving physicians free service in making Wassermann tests, examinations of the spinal fluid and blood chemistry examinations. In 1925, the psychiatric institute was transferred from Mendota to the Bradley Memorial Hospital situated adjacent to the present medical school buildings, in order to secure closer cooperation with other laboratories of the university.

The teaching of clinical medicine in a small way was made first possible by the establishment in 1910 of a student health service at the university. A widespread epidemic which cost the lives of several students was the stimulus for this organization. The epidemic was traced to a carrier who had been working as a waiter in one of the student dining halls. It was believed that future epidemics of contagious disease might be prevented, or at least controlled, if cases of illness among the students could be promptly reported to a central office. It was soon found that prompt reporting of illness could be secured only by offering medical attention to the students. To accomplish this end, the staff was enlarged, and an addition was made to the Olin House on Langdon Street near Science Hall. This house was used as the university clinic from 1912 to 1924, when the outpatient division of the student health service was moved to the first floor of the Wisconsin General Hospital. For infirmary care, students were at first accommodated in wards at the Madison General Hospital, but later the Raymer House, a small frame structure next door to the clinic building, was used for this purpose. Inevitably, this small structure became inadequate and was replaced by the modern university infirmary, built partly from state funds and partly from private gifts. Fortunately, it was built on land adjacent to the present medical school.

The main purposes of the student health service are: to prevent the spread of contagious diseases, to promote personal and public hygiene at the university and to provide medical care for the students. Nearly all universities now have a student health service and recognize its importance. Wisconsin holds a leading place in this attention to student welfare. The University of California was first to establish such a service, and Wisconsin was second. The student health service was created by Dr. J. S. Evans who is now professor of medicine at the university. The immediate supervision of the work was later taken over by Dr. Robert Van Valzoh, now professor of clinical medicine.

The organization of a student clinic and infirmary with its medical staff made possible a certain amount of teaching in clinical medicine, and since 1910 courses in physical diagnosis and clinical laboratory diagnosis have been given to students in the latter part of their second year. Later on, courses in minor surgery and elements of surgery were established. The clinical teachings by Dr. Evans and his staff in the student health service served as a nucleus for the present well developed clinical courses.

In 1921, another department of state service was begun. The legislature established the office of state toxicologist in connection with the department of pharmacology and toxicology at the medical school. The chief purpose of this office is to lend aid in cases of suspected

poisoning throughout the state. This office, now in charge of Dr. C. W. Muehlberger, is situated in the medical school building.

The requirements of their own students eventually compelled most medical schools to limit more and more the number of students admitted to advanced standing from other colleges. This made it increasingly difficult for Wisconsin students to find openings in suitable schools to finish their training. Since this situation was bound to become more and more difficult as time went on, it became imperative that the full medical course be offered at the university. The question of how properly to offer the clinical years of medical teaching in a city the size of Madison became a pressing problem. It fell largely on the shoulders of Dr. Bardeen, dean of the medical school. How well Dr. Bardeen has solved this problem is evident in the beautiful, large hospital and laboratory buildings now seen at Madison, and its medical school which has already taken its place among the recognized schools of the country.

Dr. Bardeen's problem was not the problem of 1880 of starting a premedical course, nor the problem of 1907 of establishing a medical science course. These could be given in university classrooms and laboratories already existing, and at relatively small expense. Instead, not only did his problem involve great expense, but, to make his plan successful, he had, somehow, to find the necessary clinical material. For years it had been said by those qualified to know that Madison was too small for the purpose. With almost the single exception of the University of Michigan, all important medical schools are situated in large cities. He realized, however, that if he could have a large public hospital which drew patients not only from Madison, but from the entire state as well, he would have abundant facilities for teaching. With this idea in mind, he spent many discouraging years attempting to interest the legislature in his project; but because this project involved considerable state expense, the legislature was not convinced.

Finally, in 1920, the opportunity came. Following the World War, Wisconsin showed its appreciation of its soldiers in a number of splendid ways. Believing that the finest way it could show its gratitude was to assist its wounded to regain their health, enabling them to return to civil life, it created a service recognition fund, an educational bonus fund and a rehabilitation fund. In 1920, there was a large surplus in the service recognition fund. At a special session of the legislature in that year, an act was passed authorizing the use of this surplus for the establishment at the university of the Wisconsin General Hospital, as a memorial to those who served in the war. The purpose of this hospital was to provide a hospital for citizens of the state, who could not afford care in private institutions. This hospital was just what was needed to furnish the necessary clinical material.

The hospital was built on University Avenue, adjoining the infirmary and the Bradley Memorial Hospital. Its situation, next to the Physics and Chemistry Buildings on one side, and to the College of Agriculture on the other, makes it especially well adapted to the scheme of the university. The total amount appropriated for the hospital building and its equipment, including the nurses' home, was \$1,350,000. Additional funds were appropriated for the purchase of the land.

The hospital was opened for patients in 1924. It is a beautiful six story structure, built in the form of a T, and planned to accommodate three hundred and fifty patients. The vertical arm of the T is essentially a service wing, including the kitchen, dining rooms, laboratories and operating rooms. The central portion of the T is largely devoted to administrative purposes. The sixth floor is for general surgical patients. The fifth floor is for special surgical patients, including, eye, ear, nose and throat and orthopedic cases. The fourth floor is for medical patients. Each wing of these three floors contains two twelve bed wards, and eight two bed wards. The second and third floors are for neuropsychopathic patients and obstetric patients, respectively. The first floor contains the outpatient department. The roof is equipped as a solarium for the care of patients needing open air treatment.

The act, which provides for the support of the hospital and defines its purpose, makes it mandatory for physicians and public officials, and advisable on the part of others interested in public welfare, to report to their county judge, patients who need care and cannot afford it. The act also provides for the transportation to the hospital at Madison and for medical care, at joint county and state expense, of such of these patients as are found, on further investigation, likely to be benefited by treatment given at the hospital. The hospital also provides for patients who can afford hospital care and are in need of special diagnostic or therapeutic facilities not readily obtainable elsewhere.

The hospital staff has been chosen carefully with reference to special training, and to experience in teaching and research. It is composed both of full time and of part time men. Within a little more than a year from the time it was opened, the hospital was usually filled to a point close to its capacity. With the completion of the hospital, there was no longer any obstacle to the installation of the complete medical course. In the fall of 1925, the first classes in the third year of the medical course were begun, and this class, the first to receive the M.D. degree at the University of Wisconsin, graduated in 1927.

But now that fortune had begun to smile, an added development soon came in the way of another new building large and adequate enough to house nearly all the departments of the medical school. In 1925, the state legislature provided for the erection and equipment of a magnificent medical school building in connection with the Wisconsin

General Hospital. This was to be called the Service Memorial Institutes Building as a memorial to those who served in the World War. At this time, there was a surplus in the rehabilitation fund amounting to between \$600,000 and \$900,000. The Wisconsin department of the American Legion, which had several years before sponsored the necessary legislation for the use of the surplus in the service recognition fund for the construction of the Wisconsin General Hospital, felt that the best use for this surplus in the rehabilitation fund was to devote it to a group of institutes devoted to research and teaching in medicine. For this reason, the American Legion gave hearty support to the idea, and, with the public approval of Governor Blaine, legislation was passed in 1925 to provide for such use of this fund. The purpose of these Service Memorial Institutes was to provide facilities for the advancement of knowledge of medicine and hygiene, including rehabilitation, for the educational and social work of the medical school and hospital, for the state laboratory of hygiene, for the psychiatric institute, for the laboratory of the state toxicologist and for similar educational and scientific work later to be established.

The Service Memorial Institutes Building has just been completed. With the opening of school in the fall of 1928, the first classes were held in it. It is built as a unit of the new medical center, in the same type of architecture as the General Hospital. The building is a five story structure on the corner of Charter Street and Linden Drive. It is adjacent to the north end of the General Hospital, and is connected with the latter by corridors from the first and third floors, making it a compact unit with the hospital. The institute, as it is now constructed, houses laboratories for both educational and research work in hygiene, physiology, physiologic chemistry, pathology, bacteriology, parasitology, pharmacology, toxicology, radiology and rehabilitation. With the opening of school in the fall of 1928, all of the departments of the medical school were established in the new institutes building, with the exception of anatomy and psychiatry. Provision for new quarters for these sciences has not yet been made. Anatomy, together with histology, neurology, and embryology, will still be taught in Science Hall, but, with the removal of all the other branches from that building, there is now adequate space to provide proper laboratories for these subjects there. The Psychiatric Institute will continue temporarily in the basement of the Bradley Memorial Hospital.

The idea carried out in these scientific institutes follows the method long in vogue in the schools of the Scandinavian countries and Germany. In those European countries, each institute usually has its own building. At Wisconsin, it was felt that all the departments could be more economically and efficiently placed under one roof. The plan and equipment of the laboratories in the Service Memorial Institutes Build-

ing is thoroughly modern and complete in every way. In a general way, each department has a large laboratory for classwork, and, in addition, numerous smaller laboratories containing all possible facilities for carrying on advanced work and special lines of research. The building also contains lecture and class rooms and the library of the medical school.

Two features distinguish the University of Wisconsin Medical School from other schools of this country. One of these is the definite state-wide service which each of the institutes will offer to some degree. The institutes of psychiatry, hygiene, toxicology, rehabilitation and radiology will offer especially direct and valuable public service. The work of the first three of these has been described. The value of the fourth is obvious. The radiologic institute will have a radium emanation plant from which capsules of emanation will be distributed at cost to physicians of Wisconsin for use in treating their patients.

In the other feature, the medical school of Wisconsin University is unique, for it represents a frank departure from established methods of teaching. When this departure was started two years ago, it was widely discussed as an experiment. Now its value has been proved. There is little doubt that a period of apprenticeship in the fourth year will form a permanent part of the medical course at Madison. In former times, medical schools were few. Most young men, instead of going to school, learned the art by serving as an apprentice to some physician in their community, much in the way a carpenter learns his trade today. With the development of schools, this system passed entirely out of vogue. With the rapid increase in scientific knowledge, medical practice has become revolutionized, and with this change has come a growing tendency to teach medical students more and more along purely scientific lines. This increasingly scientific character of teaching has come at the cost of losing more and more of the human side of medicine. The medical student is kept so occupied with the study of disease that he leaves his school and his hospital internship thinking wholly in terms of disease and the laboratory, and without any knowledge and with little interest as to what that disease means to the patient. When he enters practice, he is likely, for a time, to be somewhat of a misfit, and unhappy because he has been trained to diagnose and treat disease, and not to consider its psychologic and economic results in the patient. Teachers of medicine have widely realized this serious fault in medical training.

Dr. Bardeen has been the first to make a direct attempt to compensate for this loss of training in the art of medicine. Each student at Wisconsin in his fourth year spends three months as an apprentice to a series of practicing physicians in one of the several cities organized for this purpose in various parts of the state. These associate teaching

centers are situated at Ashland, Eau Claire, Janesville, La Crosse, Madison, Marshfield, Milwaukee, Oshkosh, Rhinelander and Wausau. At each of these places, a small group of practicing physicians have been chosen for their ability, experience and desire to teach, to serve as preceptors. During this three months' period, each student serves exactly as an apprentice under each of the teachers in that community in turn. The student is with his preceptor almost continually. He makes calls with him and works with him in his office. In this way, the student receives a training of a personal and valuable form, and one he could never be given within the walls of a hospital. This preceptorial system which has now been carried out for two years has aroused considerable interest among other medical schools. The system has proved gratifying not only to the university and the students, but also to the physicians who serve as preceptors. These physicians, for the most part, feel that they have gained a closer touch with academic medicine, have learned much by teaching and have thoroughly enjoyed the contact with young and enthusiastic students who are soon to enter practice themselves.

The classes in the clinical years of the medical school are, for the present at least, kept relatively small. From its beginning in the classes of Dr. Miller and Dr. Birge, the aim of the medical school at Wisconsin has been quality rather than quantity production. Ninety-six students may enter the medical school each year. Two courses are open to those students. One of these, the two year course in medical science begun in 1907 and leading to the degree of Bachelor of Science, is open to forty-eight students. On completion of this course, the students must go to other medical schools, as formerly, for the completion of their work. The other, the four year course, established in 1925, leads to the degree of Doctor of Medicine. This course is also limited to forty-eight students. Instruction in the clinical years is offered at Madison largely in the wards and outpatient departments of the Wisconsin General Hospital, at the Student Infirmary and at Bradley Memorial Hospital, and at ten preceptorial centers in larger cities of the state. Work in some of the special clinical branches is given at associate centers in Milwaukee and Chicago. Teaching in dermatology is, in part, carried on at the Milwaukee City Dispensary. Students have three weeks of special training in pediatrics at the Children's Hospital in Milwaukee. Fourth year obstetrics is given in Chicago at the Chicago Lying-in Hospital. A certain amount of instruction at Madison is also given in the Student Infirmary and the Bradley Memorial Hospital, both of which are under university control and situated adjacent to the larger buildings of the medical center.

Dr. Birge, Dr. Bardeen and those others who have so long championed the cause of the full medical course at the University of Wisconsin may well feel the greatest satisfaction in what their labors have won. Certainly, it has been largely due to the foresight and dogged persistence of these men that the university can now boast of the splendid medical school it has today. One has only to go through the Wisconsin General Hospital, and the Service Memorial Institutes Building to realize the tremendous possibilities the school has for the future.

# LOCAL MORPHOLOGIC CHANGES FOLLOWING SECTION OF THE THORACIC SYMPA- THETIC NERVE TRUNK\*

FRANC D. INGRAHAM

The recently manifested interest in the surgery of the sympathetic nervous system has been stimulated largely by the work of Jonnesco (1922) concerning cervical sympathectomy for angina pectoris, of Leriche (1916) in regard to peri-arterial sympathectomy and of Hunter and Royle (1924) in their effort to relieve spastic paraplegia by rami-section. During the past two years, the division of a sympathetic trunk has been performed on a large scale, both experimentally and clinically, in an attempt to study and relieve various ill defined disorders. The following work was done with the purpose of determining the exact character of the local morphologic changes following simple section of such a trunk, especially with regard to neuroma formation.

## MATERIAL AND METHOD

The left thoracic sympathetic trunk was divided in thirty-two dogs and in seven cats. All the animals were full grown and in good health prior to operation, and their behavior after operation remained entirely normal. The procedure was carried out in the same way in all cases. Ether was given under positive pressure by intratracheal insufflation; the left side of the chest was opened near the spine through an 8 cm. incision between the seventh and eighth ribs. Retraction of the lung exposed the sympathetic trunk which was then divided through a transverse opening in the pleura opposite the eighth rib. Care was taken not to cut through a ganglion or through the junction with a communicating ramus. Except in one instance, the cut ends were left where they lay after spontaneous retraction of the incised pleura, that is, from 3 to 5 mm. apart. The ends were not sutured in any case, and in one animal 2 cm. of the trunk was removed. The wall of the chest was closed without suturing the pleura, and the subcutaneous tissues and skin were approximated with fine interrupted silk stitches. The animals were killed in from six days to five months after operation.

The gross and microscopic specimens examined represented, in the majority of cases, preparations from the central and peripheral stumps, together with the intervening scar; in the remaining instances, the stumps were prepared separately. Staining was done by Ranson's modification of Cajal's method and by Cuajunco's method. A few specimens were stained with hematoxylin and eosin.

## GROSS CHANGES

At the site of the wound in the wall of the chest, there was, in every instance, marked thickening of the pleura with the deformity which would be expected from the method of closure employed. In the

---

\*From the Surgical Hunterian Laboratory of Johns Hopkins Hospital.

animals killed within a period of fifteen days, a noticeable but not severe reaction occurred around the ends of the trunk. In those killed after a longer period, there was only slight thickening of the pleura, which, in every instance, had regenerated sufficiently to close the defect. Several methods were employed to obtain satisfactory preparations of the nerve ends themselves for study. Fixation *in situ* by filling the chest with formaldehyde was found to give the best result. In this way, a careful examination of both ends of the trunk was possible, and the trunks and

Fig. 1.—Thoracic sympathetic trunk of cat. *A*, 36 days after section; *B*, 35 days after section; *C*, 26 days after section; *D*, 25 days after section

intervening tissue could be dissected away from the adherent pleura. Not in any instance was there marked enlargement in either end of the severed nerve. The appearance shown in figure 1 is characteristic of the gross changes found, i.e., a scarcely perceptible increase in the diameter of the trunk immediately above and below the scar, without any demonstrable difference in the central and distal stumps. In only one instance was the enlargement sufficient to be considered a possible neuroma, but microscopic examination showed the swelling to be due entirely to closely adherent scar tissue.

Fig. 2.—Junction of proximal and distal ends of sympathetic trunk six weeks after section;  $\times 80$ .

Fig. 3.—Same as figure 2;  $\times 300$ .

As far as could be ascertained grossly, union between the two stumps had been accomplished by proliferation of the scar tissue, which gave the appearance of a separate dense scar around the end of each stump, with a narrow clear gray defect between them.

#### MICROSCOPIC CHANGES

Histologic examination bore out the impression that there was nothing here comparable to neuroma formation. Degeneration of neuraxes and slight proliferation of connective tissue were present in both ends, more evident in the proximal than in the distal stump.

As contrasted with the cut ends of a peripheral nerve, however, these changes were extremely slight. Characteristic spirals or masses of aborted regenerating neurofibrils were not found. On the contrary, what few regenerating fibers were present proceeded from the proximal to the distal ends, with comparatively little obstruction. It was possible to follow these neurofibrils through serial sections showing a definite but limited connection between the two ends of the nerve by the end of the fourth week. After a longer period there seemed to be little change in the extent of the regeneration.

#### COMMENT

The experiments appear to demonstrate that neuroma formation does not occur in either stump of a severed thoracic sympathetic trunk. Whether or not this is true of other portions of the sympathetic pathways remains to be determined. Ranson refers to the occurrence of a neuroma on the severed end of a cervical sympathetic trunk in one of his experiments. Other references to this point were not found in the literature, it having been taken for granted, apparently, that sympathetic trunks behave in this respect like peripheral nerves.

It might be supposed that in these experiments the two ends of the trunk were left in too close proximity to permit the type of reaction responsible for neuroma formation. If this is the case, this feature is distinctive of sympathetic trunks, as in a peripheral nerve neuroma formation occurs with even less of a gap than was present here. Moreover, in the one case in which the trunk was resected the severed ends did not differ in appearance from the others. As suggested previously, there is some histologic evidence that the ends were in close enough proximity to permit partial regeneration, but this does not preclude the possibility of neuroma formation at least in peripheral trunks, as the picture of a large characteristic neuroma with a few fibers breaking through to the distal stump is there fairly common.

However, resting on the wall of the chest and covered only by the pleura, the thoracic sympathetic chain is remarkably free from sur-

Fig. 4.—Junction of proximal and distal ends of sympathetic trunk five and one half weeks after section;  $\times 80$ .

Fig. 5.—Same as figure 4;  $\times 300$ .

rounding structures, as compared with peripheral nerves, and it is possible that this unique freedom from pressure explains the lack of neuroma formation. On the other hand, there may be an intrinsic difference in the reaction of the sympathetic trunk to injury.

# THE BOVIE ELECTROSURGICAL CURRENT GENERATOR

SOME UNDERLYING PRINCIPLES AND RESULTS \*

A. J. McLEAN

An almost infinite variety of controlled destructive effects is made available to the surgeon by modulation of high frequency oscillating currents. The character of the effect produced is not determined by the frequency of the oscillations, but appears to depend entirely on the character of the oscillatory wave trains utilized. When a surgeon desires to destroy tissue en masse by heating, a train of damped oscillations is customarily used; but to obtain cutting effects, a train of undamped waves is used, although tissue can also be readily heated by undamped waves. A damped wave is one with an oscillating potential which tends to return to zero, as shown in figure 1 *b*; an undamped wave is one with an oscillating potential which remains constant, as shown in figure 1 *a*. The fundamental arrangements for production of high frequency damped oscillations (condenser-gap-inductance) and undamped oscillations (e. g., triode tube), which are detailed in textbooks on physics and which have been already detailed in medical literature,<sup>1</sup> are relatively simple, but the production of flexibly regulable currents suitable for use in surgery is a complicated problem in electrical engineering.

The purpose of this paper is to report certain experiments in the healing of tissues after subsection to the various typical currents generated by the Bovie electrosurgical unit which has been in use at the Peter Bent Brigham Hospital for the past two and a half years. The original manuscript was submitted for criticism to a number of persons; among these was Dr. Bovie, who took exception to the interpretation of some of the physical principles involved. He has taken the trouble to write a description of the mode of action of the currents employed, and, with his permission, his text, which designedly avoids

leaning on either resonance or quantum theories of matter, is here substituted for the original.<sup>2</sup>

The conduction of an electric current through tissue is in general like the conduction through solutions. It is electrolytic rather than metallic; that is, the transfer of electricity is accompanied by a transfer of charged matter. But the transfer of charged matter, and therefore of the current, is a more complicated process than that which occurs in simple solutions. This is necessarily so, for protoplasm is not a molecular chaos as is the simple solution; its molecules are held more or less fixed in the heterogeneous, polyphase colloid which it appears to be, and its ions are therefore not free to migrate in every potential gradient. Migration is hampered at the colloidal interfaces, especially at the bounding interfaces, such as those which separate the nucleus from the cytoplasm and those which form the outer boundary of the cells. Under the influence of a potential gradient these semipermeable membranes, as they are often called, become polarized. The ions of adjacent phases become concentrated at these membranes. The molecules of which the membranes are formed may take on new orientations in the electrical field, and this disturbance of the protoplasmic molecular pattern and the accompanying electrification of the membranes is inimical to the continued existence of the protoplasm, and so the electric current is lethal.

Fig. 1.—Wave trains: *a*, undamped oscillations; *b*, two trains of damped oscillations.

Now obviously this lethal effect of the current which is due to polarization may be avoided if we do not permit the current to flow long enough to cause these disturbances in the molecular arrangement, with the accompanying electrification.

The length of time which the current may be permitted to flow without producing lethal effects is inversely proportional to the current density, that is, to the amount of current flowing through a given cross-section of tissue. If we had data we might plot a tolerance curve which would show the maximum current density permissible for different lengths of time of current flow; that is, we could plot the current density as ordinates against the length of time which the current could flow without producing the lethal effect as abscissae. Such a tolerance curve would slope downward toward the right. In other words, for high current density the duration of flow would be shorter, while currents of low density could be permitted to flow for longer periods of time.

2. Although the machine with its incorporated (unquantitative) wiring diagram is now on the market, Dr. Bovie desires that a technical description of the apparatus await his own publication, since radical improvements in its construction are in progress. The results herein reported were obtained with the original experimental unit used at the Huntington Memorial and Peter Bent Brigham Hospitals, which was essentially similar in its construction to the "S-D-3; 7-23-28" model now on the market.

We may avoid lethal effects if, instead of interrupting the current after it has been flowing a short period of time, we reverse its direction of flow, and thus reverse the potential gradient in the protoplasm. All of the migrations and orientations would be reversed correspondingly, and the lethal effects would be counteracted by the reversed current.

If now we plot the tolerance curve for an alternating current, plotting the current density as ordinates against the frequency of alternations as abscissae, the resulting tolerance curve will slope upward to the right, for if we increase the number of alternations per second and thus shorten each interval of time during which polarization may occur, we can increase the amount of current we pass through the tissues without producing lethal effect.

As is well known, if the frequency be high enough, considerable amounts of current can be passed through the tissues without producing even so much as physiologic response on the part of the tissues.<sup>3</sup> From the meager amount of data available on this matter, it appears that this latter tolerance curve is convex toward the axis of abscissae; that is, the permissible current density increases more rapidly with higher, than it does with lower, frequencies.

If the frequency be high enough, sufficient current may be passed through the tissues so that no effect, other than heating, will appear. With high frequencies this heating effect can be carried to the destruction of the tissues, without any other effects due to the passage of the current becoming apparent.

The foregoing constitutes the rationale of the high frequency currents which are used in the practice of medicine and surgery.

The heat produced by the passage of an electric current through tissues is proportional to the product of the square of the current density, the resistance of the tissues, and the time. The current density is influenced by a large number of factors. For the tissues immediately under the electrodes the current density varies inversely with the area of the electrode, and therefore large electrodes are used where the heating effect is to be kept at a minimum, while the active or working electrode is made small in order to increase the current density in the tissues in its immediate vicinity.

The current density is also influenced by the areas of the cross-section of the conductor through which the current passes. Within the body of an electrolyte Ohm's law is obeyed, and this law undoubtedly applies to the passage of an electric current through tissues, but the resistance of the conducting tissues is not uniform. The current passes through the tissue as through a network of conductors, and for any region the current density is inversely proportional to the resistance. The resistance of tissues to the passage of an electric current is not constant, but varies with the physiologic condition of the tissues; the conductivity of dead tissue being in general greater than that of living. The influence of the physiologic condition, however, is more marked for alternating currents of low frequency and for direct current, than it is for alternating current of high frequency.

The current density varies directly with the electromotive force applied to the electrodes, but the value of the electromotive force may be quite different from that of the electromotive force impressed into the circuit by the generator of the high frequency currents. Because of the potential losses in resistances, inductances, capacities, etc., which are necessarily included in the circuit, the value of the electromotive force applied to the electrodes may be quite different from that impressed into the circuit by the generator itself. The electromotive force impressed upon

---

3. d'Arsonval, M. A.: Action physiologique des courants alternatifs, *Compt. rend. Soc. de biol.* 43:283, 1891 (footnote 1, first reference).

the electrodes is therefore profoundly influenced by the amount of current flowing through the circuit, and in practice the electromotive force at the electrodes is seldom determined, or known.

Now it should be borne in mind that the increase in temperature of the tissue is not governed entirely by the amount of current passing through it. The increase must be determined by the difference between the rate of heat gain and the rate of heat loss. Heat is dissipated both by conduction to the surrounding tissues and by the cooling effect of the circulating blood. The amount of heat dissipated by the blood stream is so great that under ordinary conditions the temperature of the whole body is raised, while local heating is at a minimum.

Kirehoff's Current Law for a Steady State says that when a conductor is traversed by constant current and all of the charges in the conductor are constant, the same amount of electricity per second flows through each cross-section of the conductor. With high frequency currents, Kirehoff's Law is inapplicable to regions of the circuit containing capacity, for in this case a steady state does not exist during the time the capacities are charging and discharging. With the high frequency currents used in medical and surgical practice, the current flowing in part of the circuit may be reduced to zero and yet an adequate amount of current may pass into and out of the tissue at the active electrode. For example, it is not necessary to have a complete circuit between the terminals of the generator for certain procedures; an active electrode only being used and the indifferent electrode and its lead being dispensed with.

If the amount of current flowing through the tissues is increased, the current density in the tissues adjacent to the small (operating) electrode may be so high that the tissues are very quickly coagulated, dehydrated, and even carbonized. The moisture in the tissues is vaporized and the tissue cells are torn by the explosive escape of the steam. If the electromotive force impressed upon the active electrode is sufficiently high, arcing or sparking occurs between it and the tissues. The character of the spark and the depth of the dehydration are greatly influenced by the amount of current passing between the electrode and the tissues. Under these conditions the electrode and the tissues act as plates of a condenser and the effects produced are profoundly influenced by the characteristics of the wave train of high frequency currents used. If the wave trains are highly damped only the heating and dehydrating effects of the current are observed, but if the wave trains are undamped and the current density sufficiently high, then the tissues may be severed at the active electrode, as with a sharp scalpel, and if the electrode be moved rapidly through the tissues, the coagulation of the cut surfaces may be kept at a minimum.

Then by increasing the amount of damping, using a current in which wave trains do not follow in immediate succession, the amount of coagulation and dehydration at the cut surfaces may be increased. Comparatively vascular tissues may be severed by this method without loss of blood, by using the proper type of current.

The surgical current generator ("Bovie") contains electrical circuits for the generation of high frequency currents having the useful characteristics outlined in the foregoing. One hundred-ten volt alternating current of sixty cycles per second is taken from the mains and sent into the primary of an insulating transformer. The secondary of this transformer delivers sixty cycle current at a pressure of one hundred-ten volts. It is so constructed that it completely insulates the electrical circuit of the generator from the ground, thus obviating the necessity for using a wooden table for operating or of taking other precautions which might be necessary were the operating circuit grounded.

The surgical current generator is equipped with two independent circuits for the generation of high frequency currents. The resistances, inductances, etc., of one circuit are of such dimensions as to generate highly damped oscillations, while the cutting circuit is so arranged as to generate only those high frequency currents having a small amount of damping. The amount of damping of the current delivered to the operating electrode can be controlled over the necessary range by switching in capacities of different sizes. Both of these circuits are provided with voltage controls by means of which the amount of current delivered to the electrode can be adjusted to meet the conditions occurring in both fine and gross dissecting. Deep cuts may be made with the knife or loop when large amounts of current are used.

By the use of cutting currents of high potential, tissues having a high electrical resistance, such as tendons, cartilage, and cancellous bone, may be readily cut, and fatty tissues may be severed without melting. In the last instance the danger of causing undesirable burns through the flowing of the melted fat, is removed.

The high voltage currents in the damped circuit are used for dehydrating the tissues by sparking. Connective tissues shrink under these currents and enlarged blood vessels may be emptied of their contents and their walls collapsed, so that these tissues may be cut through without the use of ligatures. The sparking current can also be used for dehydrating surface layers of tissues.

All will agree that damped waves produce their ohmic heat within the tissues because of the latter's resistance to their passage. Undamped waves also cause heat, however, and the ultimate mode of their production of cutting effects remains at present somewhat obscure; objectively, an infinitesimal arcing discharge occurs. But an arcing discharge may also take place when damped waves are used, though cutting effects, with most present day machines, are then absent. The probable ultimate difference in effect lies in the character of the concentration of the arcing discharge, that is, in the current density, though the final importance of this also may be subject to differences of opinion. The oscillating potential of the ordinarily produced damped wave train rapidly varies and diminishes, and when its arc is examined with a revolving mirror, one sees that this results in a spray or brushlike arc, one flash striking to one side, the next probably far to the other; its concentration is thus relatively poor. The undamped wave train, on the other hand, has a uniformly sustained oscillating potential and its arc is seen in the revolving mirror to be a compact tight pencil; the resultant impinging current density is therefore much more intense. The observed differences in concentration of the arcs are probably due to the persistence of ionization of the air gap between the electrode and the tissue in the latter instance, and not to any inherent differences in wave form as already suggested. The empiric evolution of diathermic (endothermic) apparatus has been such as to overstress and make a mystery of wave form. A recurring series of damped oscillations, also, can produce a persistence of air gap ionization, as well as can undamped oscillations, provided the interruptions are of sufficient rapidity. An

electric arc is productive of an exceedingly high temperature, and it is probable that the momentary intense heat of the high current density is responsible for the molecular dissolution of the tissues objectively evident as cutting, though the precise atomic method by which the energy and heat unlocks molecular structure remains hypothetical.

A cutting machine of the Bovie type, however, which utilizes a condenser-gap-inductance arrangement can produce only damped waves; yet such machines cut. It seems not improbable that such machines may obtain their effects either (1) by such crowding together of damped wave trains that the oscillating potential is never allowed to reach zero, a certain "core" of potential similar to an undamped wave train being thereby maintained, or (2) as is more likely and is stated in the foregoing paragraph, by interruptions increased only to such rapidity that the gap between the electrode and the tissue does not have time to revert preponderantly to a nonionized state. That is, the crowding of damped trains need not necessarily be carried far enough to maintain a degree of incessantly oscillating potential, provided the duration of nonfiring of the electrode gap is short enough to prevent its deionization and its sequential dispersion of heat energy over a larger area of tissue. Rationally then, either damped or undamped oscillations can produce either cutting or deep heating effects, provided that for cutting there is maintained a high current density and an adequate electrode-gap ionization, and for deep heating a relatively low current density and no persistent ionization of the electrode gap (through more sluggish interruptions of oscillating trains, either damped or undamped).

#### EFFECTS ON TISSUE

The primary utility of electrosurgery with high frequency currents lies in the fact that it is accomplished by controlled continuous heat. Capillaries, arterioles, venules and lymphatics are sealed, hemostasis is improved, traumatic metastasis is prevented and outlying malignant cells are dispatched.<sup>4</sup> Outside of neoplastic work, its superiority over sharp dissection is evident experimentally only in oozing capillary beds, particularly in parenchymatous organs as the liver, spleen, brain, thyroid, kidney, lung, enteric mucosa and others, though ingenious, and sometimes revolutionary, applications have been made in all fields.<sup>5</sup>

As the cutting electrode advances through tissues an infinitesimal arc of high current density precedes it. Protoplasm separates before it without that useful sense of resistance afforded by the sharp knife. The cut surface is bloodless and lightly seared, and its temperature is occasionally slightly warmer than normal to immediate touch. Ward<sup>6</sup> has given a photomicrograph of an incision made by the (Wyeth endotherm) pure undamped wave. Figure 2 is a photomicrograph of an incision made by the blended wave of the Bovie cutting unit, using a moderately severe grade of dehydration. Figure 3 shows that the essential histologic changes produced by the coagulating unit are not

Fig. 2.—Photomicrograph of edge of incision made in cat's liver by Bovie unit using low voltage, medium dehydration, variometer 65; immediate fixation in Zenker's fluid; hematoxylin and eosin stain;  $\times 142$ . The electrode passed by on the left; there is 50 microns' depth of formless molecular dissolution. To the right of this is a zone 650 microns wide, made up of coagulated cells with intact nuclei and ground glass cytoplasm, with the erythrocytes in the portal venules and intralobular capillaries undestroyed except in the outer 150 microns. Throughout the whole zone are steam vacuoles within the parenchyma, containing occasional wisps of precipitated albuminous fluid. To the right of this is a third zone, 250 microns wide, where the cells are at times slightly rounded, with occasional ones the cytoplasm of which stains rather deeply. Nuclei and chromatin network, however, are unaltered, and this zone is viable. Beyond it to the right is normal liver. The zone of alteration extends 0.9 mm. beyond the apparent line of incision.

6. Ward (footnote 4, second reference).

dissimilar. The depth of alteration beyond the line of incision may be made only 100 or 150 microns by proper adjustment (LD, LV, 32), and a fine needle or blade. Histologic studies of experimental incisions and resections in the spleen, lung, cartilage and kidney show an essentially identical process; in most of these, however, either the structure of the tissue or the tenacity of the fibrillary reticulum, or both, have prevented the abundant formation of steam vacuoles in the proximal zone of coagulation, seen in figure 2. That the process is less in degree only is illustrated in figure 4, showing the edge of incision in a kidney resection.<sup>7</sup>

Fig. 3.—Photomicrograph of cat's liver after four seconds' contact application of coagulating current through a loop electrode, using low-tuned gap, low voltage, choke-coil tap 3; immediate fixation in Zenker; hematoxylin and eosin stain;  $\times 28$ . The absence of molecular dissolution in the middle of the surface is due to the adhesion of this zone to the electrode. Radial penetration of detectable histologic alteration is 2.8 mm. The shrinkage of the coagulum has freed some of the altered cells into a lake of plasma underneath it.

7. Deeper histologic alterations would probably be demonstrable by special staining. Dr. Percival Bailey (personal communication) has found alterations of tinctorial quality a full centimeter from the edge of an incision in brain tissue, when phosphotungstic hematoxylin or silver impregnations were used on tissues removed by the cutting current (exact setting of dials not recorded, however).

As a number of observers have pointed out, healing depends on the depth of necrosis. Voltz and Döderlein<sup>8</sup> obtained photomicrographs of healing in a kidney three and five days after operation. Figure 5 shows twenty-day healing of a wedge-shaped resection of a dog's liver; there is more scarring than following resection with a sharp knife. This is true in other organs as well, and is illustrated again in cutaneous healing, as shown in figure 6.

Macroscopically, the cut surface of parenchymatous tissue is lightly seared. There is no capillary oozing, but after a moment or two the

Fig. 4.—Photomicrograph of edge of incision made in cat's kidney by Bovie unit, using low voltage, medium dehydration, variometer 55; immediate fixation in Zenker; hematoxylin and eosin;  $\times 125$ . The layer of complete molecular dissolution is here only about 35 microns thick, and beyond it lies a 25 micron layer of desiccation or "mummification" necrosis, as described by Clark, Morgan, and Asnis (*M. Herald.* 43:271, 1924; 44:10 and 30, 1925). Beyond this second zone, is another 200 microns of classic coagulation necrosis with intact nuclei and vitreous deeply-staining cytoplasm. The proximal layers of the latter contain an occasional steam vacuole. The structure of the tissue is such, however, that all noxious effects are not delimited by this layer, for the boiling urine has resurged up every fortieth or fiftieth collecting tubule or loop of Henle and coagulated the epithelial lining for 3 or 4 mm. back of the line of incision.

8. Voltz, F., and Döderlein, G. Jr.: *Kauterisation und Lichtbogenoperation*, *Monatschr. f. Geburtsh. u. Gynäk.* 66:247, 1924.

cut surface may become moist with exuded plasma. As greater intensity (variometer) is used, the cut surface may be browned or may be charred relatively superficially, while as heavier dehydration is used destructive effects penetrate more deeply laterally, though leaving the cut surface of about the same appearance. A heavier dehydration is therefore more effective in checking bleeding than is increased intensity; in fact the latter may serve only to blow a hole in the side of a vessel and augment bleeding. Venous blood is more readily staunched than arterial, and veins up to 1 or 1.5 mm. in diameter are taken care of by the

Fig. 5.—Photomicrograph of twenty day healing in dog's liver, after wedge-shaped resection with low voltage, low dehydration, variometer 40, and approximation with silk; Zenker; hematoxylin eosin;  $\times 20$ . The removal of necrosed parenchyma cells is complete. The collapsed lobular framework and scarring contains unaffected cells and is being invaded by regenerating hepatic tissue. There is still some foreign-body reaction, with macrophages, about the two black silk mattress sutures used for closure of the cleft.

Fig. 6.—Photomicrograph of eighteen day healing, after skin incision with low voltage, heavy dehydration, variometer 40; hematoxylin and eosin;  $\times 19$ . Healing was per primam; the scar is 1.8 mm. broad.

moving electrode. However, the arcuate arteries of the kidney, the arterioles inclosed in the more peripheral branches of Glisson's capsule in the liver, and arterioles of the pia arachnoid may require special

treatment; Ward's<sup>9</sup> method has been modified here, so that a spurter is merely picked up with dissecting forceps already in hand, and a coagulating current momentarily run down the instrument, by contact with the active electrode of the electrosurgical unit. This can be done as readily with the Bovie cutting current as with the coagulating current, provided in either case it is not continued to charring, for then the obliterated end of the vessel comes away with the forceps, and the vessel continues to bleed. Adequate utilization of the resources of the machine for hemostasis is learned only by experience.

The ease of healing depends on the degree of destruction of tissue, and its location. The edema occurring after heavy coagulating current might be of little consequence within the abdomen, but within the trachea or cranial cavity might cause alarming effects. Heavy dehydrating effects or great intensity may kill sufficient tissue to form a sterile abscess, if the field is reexamined before absorption has taken place. Even a moderate layer of subcutaneous fat will usually cause sufficient of an oil burn to prevent primary cutaneous union, but it is possible with care and proper electrodes to obtain primary union in a great percentage of cases. Its use for skin incisions, however, is more in the nature of a surgical feat,<sup>10</sup> for electrosurgery only efficaciously supplements, and by no means supplants, the knife. Knowing his machine, the surgeon must balance between healing and hemostasis, and in general the smallest damage and lightest current that is effective will be chosen.

Some electrical effects must be borne in mind. Cutting is controlled by the intensity and concentration of the infinitesimal arc delivered; the rate at which it progresses through the tissues is controlled by the dial settings, not by the pressure of the operator on the electrode. Current from the active electrode will take the route of least resistance to the indifferent electrode. This is not necessarily the shortest route, and depends on the resistance of the tissues which must be traversed; small structures of excellent conductivity, lying more deeply, may become selectively overheated, to their detriment. The surface worked on should have broad contact with other conducting tissues, so that the returning current has not opportunity to reconcentrate ("funnel through") disastrously<sup>11</sup> en route to the indifferent plate.

#### SUMMARY

The mode of action and the results obtained by the Bovie electrosurgical current generator are discussed.

# MUSCLE TONE IN MAN \*

GEORGES SCHALTENBRAND

Von Uexküll<sup>1</sup> has discovered that *Mollusca* have two types of muscle, a motor muscle which closes the shell and another which holds, with enormous power and without output of energy, the previously closed shell. He could demonstrate different organs for these two functions also in other organisms of a lower order. He differentiates these two functions as motor and locking (Sperr—) functions. Von Uexküll believes that in other animals, in which only one motor organ can be demonstrated, both functions are united in this organ. In *Sipunculus*, the muscle not only can shorten and lengthen but also keeps a certain level of tone at the same time, which can be varied independently. Certainly these are two functions of a single organ but it is doubtful whether they can be identified with the motor and the "locking" function of the shell muscle. This has been taken for granted, however, by von Uexküll and his pupils, and they have tried to discover these two elementary functions in the muscles of vertebrates, including man. As a matter of fact, the muscles of higher vertebrates have, when viewed from this angle, two important functions; namely, "motility" and "posture" (Haltung). The postural function exerts a permanent tension against gravity. If von Uexküll's conception were true, the striated muscle ought to change its length and viscosity, each property independently of the other, irrespective of the weight supported. Trials to demonstrate this ability in the isolated muscle have failed, as well as attempts to demonstrate different types of innervation, metabolism or electric activity for the motor and the postural function of the muscle (see the article by Stanley Cobb<sup>2</sup> and the excellent monograph of Fulton<sup>3</sup>). In the muscles of higher mammals, active shortening of the muscle is also combined with increase in firmness and vice versa; when the shortening is inhibited by force, the firmness of the muscle appears separately with increase of tension. Fulton showed how the uniform principle of simultaneous or successive all-or-none innervation

of single muscle fibers, under reflex direction from the nervous system, could explain all the motor phenomena observed in movement and posture. However, one has to admit that the viscosity of muscle can vary. This may bear some relation to von Uexküll's theory of the locking function. Thus, all striated muscles show the well known staircase phenomenon, that is, the muscle seems to become softer during successive contractions, and contracts for increasing altitudes. Hill has also shown that quick movements cost a relatively higher output of energy than slow ones because, in addition to the outer work to be performed, the inner friction (viscosity) of the muscle must be overcome. It is also known that after long fixation of muscle, for example, with plaster casts, the muscle hardens and shrinks and gives a higher resistance to stretch even when denervated and anesthetized. However, the relation of these changes of viscosity to the postural function is still an unsolved problem; possibly there is no relation at all.

A part of the confusion of the literature on muscle tone comes from the fact that the differentiation between the different conceptions of postural function, locking function and viscosity is not made sufficiently clear.

Different methods for examining muscle tone have been described. In some of them the resistance of the muscle against pressure is examined (Wertheim-Salomonsen).<sup>4</sup> Another method, devised by Gildemeister,<sup>5</sup> determines the elasticity of muscle with a falling ball reflected by the muscle, while the time is measured electrically as long as contact is maintained between ball and muscle. These methods do not permit of differentiation between viscosity and tension of the muscle. A third method measures the resistance of the muscle against stretch by means of isometric dynamometers. It has been used by Liddell and Sherrington<sup>6</sup> in experiments on animals, and Spiegel<sup>7</sup> and others have tried to introduce the method into clinics. Only the third method differentiates between viscosity and tension, because after the muscle has stopped moving it records only tension. The curve which is obtained during the movement and for a short time afterward, however, might be a result of both tension and viscosity. Nevertheless, the third method is the most practical because it allows permanent measurements with simple machines and without great error.

5. Gildemeister, M.: *Ztschr. f. Biol.* 163:183, 1914.

6. Liddell, E. G. T., and Sherrington, C.: *Reflexes in Response to Stretch (Myotatic Reflexes)*, *Proc. Roy. Soc.*, 1925, no. 27; *Further Observations on Myotatic Reflexes*, *ibid.*

7. Spiegel: *Der Tonus der Skelettmuskulatur*, Berlin, Julius Springer, 1927.

Sherrington<sup>8</sup> and Liddell<sup>9</sup> examined the postural functions of the decerebrated cat with this method. They found that the muscle responded to an increasing stretch with an increasing tension, which must have been reflex, because it disappeared after severance of the anterior or posterior roots. They called it the myotatic or "stretch" reflex. They further showed that as soon as the passive stretch of the muscle surpassed a certain level, the muscle suddenly relaxed and lost its tone. Sherrington called this reflex the "lengthening reaction." It is still dubious whether or not this motor phenomenon is always reflex. Certainly, immediate relaxation of the muscle can always be obtained by centripetal electrical stimulation of its nerve. But Samojloff and Kisseleff<sup>9</sup> could not demonstrate any diminution of action currents in the lengthening reaction, due to overstretch.

A third reaction is the shortening reaction. It was originally discovered by Sherrington, together with the lengthening reaction. Sherrington found that in some decerebrated animals one can place the extremities in various postures; the muscles are cataleptic. He thought that this catalepsy was due to the fact that the muscle that is shortened passively undergoes an active contraction corresponding to the antagonist's relaxation after passive extension. This active contraction during decrease of tension would be the shortening reaction. Recently, Fulton<sup>2</sup> has stated that there is no real shortening reaction. He thinks that the observed fact might be explained sufficiently by a stretching reaction, which begins at the very moment when the passive shortening of the muscle ceases and the muscle again has to carry a certain weight. This explanation does not convince me, because it is hard to understand why the muscle has different resting lengths, before and after movement, for a particular weight, unless a special reflex has taken place in the meantime. Here, again, the problem is complicated, because Samojloff and Kisseleff<sup>9</sup> observed a decrease or absence of action currents during the passive contraction. The decision must be made by experimentation.

Of course, the physician is interested to know how far difficulties of muscle tone in man can be identified with decerebrate rigidity. German clinicians differentiate in man chiefly two forms of disturbed muscle tone, namely, spasm, as it is seen in lesions of the pyramidal tract, and rigor, which is seen in extrapyramidal diseases, especially in parkinsonism. A great number of authors, including Strümpell,<sup>10</sup>

8. Sherrington, C.: On Plastic Tonus and Proprioceptive Reflexes, *Quart. J. Exper. Physiol.*, 1909, no. 2; Postural Activity of Muscle and Nerve, *Brain*, no. 38; The Integrative Action of the Nervous System, Sullivan Memorial Lectures, 1923.

Foerster,<sup>11</sup> Lewy,<sup>12</sup> Mayer<sup>13</sup> and Gamper,<sup>14</sup> have tried to identify these two difficulties of tone with subjective methods. Other authors, especially Spiegel,<sup>7</sup> have used objective methods. Their machines, however, are insufficient, because they ignore the factor of time, or, as in the case of Filimonoff,<sup>15</sup> the exact position of the limb. I tried, therefore, to develop a machine which would record muscle tone in man in a manner as similar as possible to the methods of Liddell and Sherrington.<sup>6</sup>

The machine produces passive movements in the elbow or in the knee joint, and allows a permanent record of the difference of tension between flexors and extensors of these joints.

#### A METHOD OF RECORDING MUSCLE TONE

In order to avoid the influence of gravitation, the axis of the joint is put vertically in space. The extremity examined is hung by means of leather cuffs to two bars which are joined by a ball-bearing junction the axis of which corresponds, as far as possible, to the axis of the joint. The proximal bar is fixed in space, so that only the distal bar with the distal part of the limb can move. It is moved by means of a third bar, which rotates around the same axis but is connected with bar 2 only by two dynamometers, one for the extensor and one for the flexor side. The record of the dynamometer is written on a kymograph by means of a thread conducted through the axis of the instrument. Thus its curve is not disturbed by the positions of the moving part of the machine. The position of the moving part is recorded exactly by means of another thread. Both threads are kept under tension by light springs, so that the writing levers cannot overshoot or slacken. On the lowest line, time is recorded in seconds. The entire machine is attached rigidly to a big Zeiss projection table and can be moved up and down.<sup>16</sup> When the arm is going to be examined, the patient sits down on a chair and holds the arm at the level of the shoulder and in supinated position. The arm is attached to the machine at this level with the elbow joint just below the junction of the machine. When the flexors and extensors of the knee joint have to be examined, the patient lies on a couch, on his side; the leg to be examined must be above, and is attached to the machine, again so that its movements are performed in the horizontal plane.

16. All the moving parts are of duraluminum, and the joints are ball-bearing in order to minimize the effects of inertia and friction.

A series of healthy and diseased persons were examined with this machine. Before every experiment, the different positions of the joint are marked on the curve; after the experiment, the dynamometer is tested with weights, pulling the moving bar at a distance of 50 cm. from the axis. The kilogram marks shown in the charts refer to this measurement.

The basal experiment was always a flexion of about 20 to 80 degrees, followed, after about half a minute's rest, by an extension of the same amplitude. The speed of the movement varied between one and five or six seconds.

Chart 1.—Curve for left healthy arm of patient with right-sided hemiplegia in cerebral syphilis. In this and the following charts, the first line gives the reading of the dynamometer compared with a pull in kilograms, at a distance of 50 cm. from the axis of the joint; the second line shows the position of the arm in degrees, and the third line gives the time in seconds.

#### RESULTS OF EXPERIMENTS

The results are best explained by a few curves. Chart 1 shows the curve of a normal arm, first extended for about 80 degrees and then flexed. During each of these simple movements the dynamometer writes an S-like curve. The first jerk is recorded at the beginning of the movement, the second one in the opposite direction at the end of the movement. A similar curve has been obtained when the machine is moved without connection with a patient. It develops from the inertia of the moving parts of the machine. To this is added, during the experiment, the inertia of the moving part of the extremity. It is evident that the inertia at the beginning and at the end of the movement must be

recorded in alternating directions. In most normal cases, the reflex at the beginning is slightly greater than that at the end. This indicates that a second factor interferes with the effect of inertia. This must be the friction or viscosity of the muscle and, eventually, a certain amount of reflex resistance.

Chart 2.—Curve for right paralyzed arm of the patient in chart 1. *B* indicates flexor tone; *Str*, extensor tone.

Chart 3.—Influences of the speed of movement on muscle tone in the patient in charts 1 and 2.

The curve demonstrated in chart 1 is from the left, healthy arm of a patient with right-sided hemiplegia in cerebral syphilis. The paralyzed right arm gave a different curve (chart 2). It shows an increasing flexor tension with increasing stretch of the muscle. Immediately after

the stretch, the tension is highest; it then decreases and remains on a horizontal level for some time. I call the initial rise of tension above the definite level a "nose." It can easily be seen that the tone increases in direct proportion to the increasing stretch and then stays on a plateau. Associated with each grade of flexion there is a fall in flexor

Chart 4.—A spasm of the flexor only in the left arm of a patient with disseminated sclerosis.

Chart 5.—Hemiparkinsonism of the left side after encephalitis. Left portion of chart, diseased left arm; right portion, normal right arm.

tone, soon followed by a slight rise. Thus a negative of the "nose" is obtained after every step of extension. As soon as the arm is flexed beyond 100 degrees, tension is recorded on the extensor side of the graph; the tone is similar to that previously observed on the flexor side. One must keep in mind that the dynamometer records only the differ-

ence between flexor and extensor tone. Thus the negative flexor "nose" may be due to a positive extensor "nose," buried under the high flexor tone.

There is no question about the tremendous difference between the curves for the normal and the pathologic condition.

Chart 6.—Left arm of a patient with parkinsonism of unknown origin.

Chart 7.—Same patient as in chart 6. Left side of chart shows curve for quick movements; the right side, that of slow movements.

Chart 3 shows that the speed of the movement has a definite influence on the curves. When an extension of about 70 degrees is performed in about six seconds, flexor tone shows a much lower "nose" than in a movement performed in a fraction of a second. The extensor tone behaves similarly.

The "nose" can be demonstrated in most of the spastic processes; however, occasionally it is much less evident (chart 4). In this patient, who suffers from multiple sclerosis, it is almost absent. Otherwise, he shows the same increase of muscle tone, which is proportional to the passive extension of the muscle. The tone curve of spastic patients, obtained with this machine, almost seems to be a mirrored reflection of the curve of extension.

In considering some examples of the parkinsonian syndrome, it is wise to start again from the normal condition. Chart 5 shows the curves obtained from the left and right arm of a patient who suffered from left-handed postencephalitic parkinsonian syndrome. His normal right arm gives the typical curve of an S horizontally placed, with some

Chart 8.—A patient with Parkinson's disease of the left leg. The leg shows a curve of almost spastic type. At the point indicated by an arrow at lower right, the leg is released and returns spontaneously toward the position for which it shows a predilection.

vibrations due to vibrations of resonance in the dynamometer. The curve of the diseased arm differs from the normal one chiefly in the absence of the second jerk at the end of the movement. The impulse of the arm has been absorbed on the way from the extended to the flexed position; the movement of the arm is permanently inhibited on the way. With quick rotation of the arm, there is indeed increased tone outlasting the movement, but a few seconds later it drops to zero again. This is the typical behavior of patients with Parkinson's disease. It is much more pronounced in the curves shown in chart 6 taken from a more advanced case. Here a strong tremor is also recorded; the dynamometer's curve, however, can be easily read. The tension of the extended muscle

rises very high, and falls to zero in a logarithmic curve soon afterward. The result is something like the "nose" in the curve for the first patient; however, the "mirror effect" is absent. The "nose" increases with the speed of the movement, just as it did in the first spastic patient (chart 7).

In the severest cases of paralysis agitans, there are occasionally curves similar to those in spasm (chart 8). However, it is always evident that extensors and flexors participate in disturbance of tone, while in real spastic paralysis there is a definite predilection of the disturbance of tone either for the flexor or for the extensor group of muscles. By means of this predilection one can recognize a slight spastic paresis in the curve, even when it otherwise simulates that of a patient with Parkinson's disease (chart 9).

Chart 9.—The left side of the chart shows the curve for the paralyzed right arm of a patient with right-sided hemiplegia after trauma of the skull; the right side shows that for the normal left arm. The slow changes in level of the first line are due to a poor fixation of the machine.

#### CONCLUSIONS

The essential result of these experiments is the production of pathologic tone by stretch of muscles. In cases of Parkinson's disease, it is produced by stretch in all muscles of the diseased extremity; in spastic paresis in general, when the "antigravity" muscles are stretched. Another difference is that in cases of Parkinson's disease, muscle tone falls to zero soon after the movement, while in spastic paresis it stays on a certain level, after an initial drop, or from the beginning. There are transitional forms between classic spasm and classic rigidity. The effect of the typical spasm is that of a spring, an effort to fix an especial

posture, whereas that of rigidity is essentially that of a brake, the fixation of every posture induced passively. Once relaxed, the spastic limb immediately returns to its predilection "posture," which the parksonian limb generally will not do.

If one compares these observations with the descriptions of difficulties of tone given by other authors, especially those of the German school, one easily recognizes all those types of behavior which have been described as "Dehnungsreflex," "Fixationspannung," "Adaptionspannung," etc. The stretch reaction of Sherrington and also the lengthening reaction can be easily recognized. The stronger the lengthening reaction, the more rigidity there is. The reaction is also weaker and there is more spasm.

It is a question whether the two main difficulties of tone in man have an analogy in experiments on animals. The spastic type can easily be identified with the classic decerebrate rigidity. However, in decerebrate animals some authors have seen certain modifications of rigidity, which may correspond to rigor. Bazett and Penfield,<sup>17</sup> and Beritoff<sup>18</sup> did not find the antigravity type in chronic subjects. Sherrington himself described a cataleptic behavior which, in my experience, excludes long and powerful stretch reactions. Girndt,<sup>19</sup> who investigated in Magnus' laboratory the spinal reflexes of cats from which the thalamus had been removed, observed on the day of the operation a cataleptic behavior of the defense reflexes, which disappeared immediately after decerebration below the red muscles. This suggests that the type of decerebrate rigidity found in animal experimentation depends on the site of the lesion. Microscopic observations on man are in favor of this opinion.

This evidence makes it appear that both spasm and rigor are composed of elements of decerebrate rigidity. But it is still impossible to discover the eventual share of muscle viscosity in subjects—animal and human—in which the rise of tone during the movement and shortly afterward surpasses the definite level of tension. Theoretically, it is possible to explain all the curves by the stretch reflex and the lengthening reaction. The shortening reaction cannot be examined with my machine.

Can any conclusions be drawn from these observations as to normal physiology? Nothing new can be created by destructive lesions. Symptoms must be hidden somewhere in the normal function. The muscle is considered as motor, but disease shows that it has two other functions, which can be compared with those of a spring and a brake.

#### SUMMARY

Three most important parts, therefore, of every automotor machine are combined in one organ. Instead of the old differentiation of muscular function into shortening and locking, three different functions of the same organ may be differentiated: movement, balancing of posture and braking movements.

# TUMORS OF THE ACOUSTIC NERVE\*

JEAN MORELLE

This study shows, in accordance with the important contributions of Henschen<sup>1</sup> and of Cushing,<sup>2</sup> that the acoustic tumors are composed histologically of a fibrillary tissue and of a reticular tissue, intermingled in varying proportions. The variation in structure has resulted in a corresponding variation in the terminology used to designate these tumors.

At the suggestion of Dr. Cushing, an attempt was made to determine whether the topographic distribution of these types of tissue in an early tumor might throw light on their significance. Moreover, since the clinical examination had revealed the persistence of a certain degree of auditory acuity, it was interesting to determine exactly the course of the remaining nervous fibers.

## REPORT OF CASE

The tumor which forms the basis of this study was found accidentally at the autopsy of a woman, aged 73, who died following an operation for cancer of the breast. The presence of the acoustic tumor was not suspected, although she was known to have a bilateral diminution of auditory acuity.

The patient was admitted to the Peter Bent Brigham Hospital on July 19, 1926. The clinical record states that there had been a progressive deafness for the past twelve or fifteen years. The vision remained good; there was no complaint of headache or vertigo. Nevertheless, just before admission she had fallen frequently, apparently from general weakness. It was after a fall eight months previously, in which she had struck the right breast, that the cancer was discovered.

The patient was much emaciated. The fundus oculi was normal. She could hear ordinary speech at a distance of about 30 cm. from each ear; a louder tone was heard for more than a meter by each ear. A cancerous nodule was present in the right breast, with ulceration in the region of the nipple.

The right breast was amputated on July 24, 1926, and the patient died the next day.

The necropsy (Dr. Charles L. Connor) disclosed chronic nephritis and generalized arteriosclerosis. There was some atrophy of the frontal convolutions of the brain and a small tumor, 2 or 3 cm. in diameter, in the left cerebellopontile angle. The supero-external pole of the tumor projected into the porus acoustic internus.

---

1. Henschen: Zur Histologie und Pathogenese der Kleinhirnbrückenwinkel-tumoren, Arch. f. Psychiat. 56:21, 1915.

2. Cushing, H.: The Tumors of the Acoustic Nerve, Philadelphia, J. B. Lippincott & Company, 1917.

The tumor was seen to lie in the left cerebellopontile angle (fig. 1), its greater diameter passing a little above the level of the pontobulbar fissure. The brain stem was not involved, except for some delicate nervous bundles which plunged into it at the normal site of emergence of the acoustic nerve. The tumor measured 3 cm. in its greatest diameter and 2.2 cm. in its transverse diameter. It was grayish-yellow; two grayer patches were seen on its external pole. Its surface was slightly nodular, and on its external extremity there was a small rough tubercle which corresponded to its point of implantation in the internal acoustic meatus.

The tumor had indented the pons on the left side and pushed it toward the opposite side, as might be seen from the curvature of the basilar artery and the median raphi with their convexity to the right. The facial nerve, flattened and

Fig. 1.—Base of the brain showing the tumor in the left cerebellopontile angle.

elongated, curved like a ribbon around the supero-internal surface of the tumor. The trigeminal nerve, although the growth was small, was nevertheless considerably elongated and appeared as a thin ribbon on the superior pole; the inferior pole had pushed the superior roots of the bulbar nerves downward.

Aside from a slight internal hydrocephalus and some atrophy of the frontal convolutions, the rest of the brain appeared normal.

The tumor was studied microscopically in serial sections, including neighboring portions of the bulb and pons, after fixation in 10 per cent neutral solution of formaldehyde. Its general structure appeared similar to that described by Henschen, Cushing and others for tumors of the acoustic nerve. The sections were stained serially in order by the following methods: Bielschowsky and Cajal for the nervous fibers, phosphotungstic acid hematoxylin of Mallory for neuroglia, Loyer for myelin sheaths and Perdrau for connective tissue.

## DESCRIPTION OF TUMOR

I shall describe successively the histologic appearance of the tumor, the course of the nervous fibers and the topographic distribution of the different tissues encountered.

1. The tumor was composed of a fibrous tissue with elongated cells and oval nuclei; these nuclei were numerous in places, sometimes in rows, sometimes more or less crowded together; a distribution in palisades was not found in the present case. The tissue appeared in the form of bands or nodules of an irregularly concentric disposition, separated by a more or less loose reticular tissue. In these places were found fine fibrils dissociated by the side of fairly numerous nuclei. In other places, the cells seemed to be separated by an amorphous substance.

Fig. 2.—Fibrillary area; method of Perdrau;  $\times 300$ .

By the use of the method of Perdrau, there was found in the fibrous areas a peculiar arrangement (fig. 2) of the fibers which were intensely impregnated and distinct from each other. These fibrils were disposed in whirls, in bands or in plumes which spread out into the neighboring reticular tissue. The nuclei of the cells were not visible by this method. In the reticular areas (fig. 3) the fibers were thicker and shorter and were disposed irregularly between rounded nuclei; the protoplasm was indistinct. In the adjacent pons and bulb, only the perivascular connective tissue was impregnated by the method of Perdrau.

The use of the method of Cajal did not permit my associates and me to determine with certainty the presence of unmyelinated nervous fibers, probably because of the use of paraffin sections. The method of Bielschowsky was no more successful, and a comparison with the results of the other methods used showed that it was not to be depended on for the identification of nervous fibers; the fibrous tissue was impregnated in numerous regions.

Nothing resembling ganglion cells was encountered; neuroglial fibrils could not be detected, either with phosphotungstic acid-hematoxylin or with neutral ethyl violet.

2. The course of the myelinated fibers, facial and acoustic, was determined by the method of Loyer. It was possible to distinguish, over a part of their extent, the cochlear from the vestibular fibers of the acoustic nerve, because of the simultaneous section of a part of the neighboring medulla.

The cochlear branch of the acoustic nerve, reduced to a delicate band of nervous tissue, passed from its emergence from the pons below the inferior pole of the tumor. At the level of the internal third of the inferior surface the cochlear fibers, until then simply applied to the surface of the tumor, became adherent and changed their direction suddenly (fig. 4). From this point they

Fig. 3.—Reticulated area; method of Perdrau;  $\times 300$ .

spread out in various directions: one small group was lost in the extreme peripheral portions of the neoplastic tissue; others scattered over the inferior surface to appear at intervals along the anterior surface; finally, the most important bundle covered the posterior surface of the tumor to gain the superior surface forming two principal groups lodged in fissures, from which the fibers turned in the greater axis of the tumor, fused their elements and passed toward the nodule projecting into the meatus acusticus internus (fig. 5 *A*, fibers in black). The fibers seemed to diminish in number as they gained the temporal extremity of the growth.

The vestibular fibers approached the tumor in a rather vertical compact bundle (fig. 5, fibers in red) situated on the antero-internal part of the tumor. They spread out like a fan on its anterior face, but the most important group curved also into the greater axis of the tumor and passed toward the temporal extremity to mingle with the fibers of the cochlear division.

The fibers of the facial nerve (fig. 5 *A*, fibers in blue) formed a relatively thick band along the anterior and inferior surfaces of the tumor but soon became flattened and spread out; they then rose to cap the supero-internal pole and finally passed toward the temporal extremity in a group which became more and more compact.

However intimate the relationship of the facial nerve with the tumor may appear macroscopically, it was nevertheless in contact only with the capsule. The disposition of the acoustic fibers was quite different: Those of the vestibular branch and especially those of the cochlear branch spread all around the tumor in its peripheral layers, forming a sort of shell (fig. 5 *B*). It is possible to find in many places a fairly sharp line of demarcation between the nervous fibers and the neoplastic cells, although the fibers are always within the capsule. Such an example of nonpene-

Fig. 4.—Turning point of the cochlear branch; phosphotungstic acid hematoxylin;  $\times 14$ .

tration is shown in figure 6; the nervous elements run against a fibrous nodule and pass above, below or to one side without penetrating it or plunging into the nearby reticular tissue. In other places, especially when the peripheral tissue is loose, the demarcation between nervous and neoplastic tissue is not sharp (fig 7).

In the tumor examined, at the point where the cochlear fibers were lodged in two fissures along the superior surface, there could be seen the most central fibers dissociated by the interposition of protoplasm-poor cells which continued without transition into the rest of the tumor. Certain of these fibers even took a direction perpendicular to that of the main band of fibers. The same dissociation could be seen in the vertical bundle or vestibular fibers where they rounded the antero-internal face of the tumor, but the central fibers continued in the same direction as the main body.

Fig. 5.—Diagrammatic drawing of tumor in relation to pons and bulb (*A*). Cross-section of tumor at 1-1 (*B*). Course of different nerve fibers colored as follows: facial nerve, blue; vestibular nerve, red; cochlear nerve, black.

Fig 6—Myelinated fibers coming from the right and turned aside by a fibrous nodule; method of Loyer;  $\times 100$ .

Fig. 7.—Superficial interpenetration of vestibular and neoplastic fibers; method of Loyer;  $\times 100$ .

A more intimate interpenetration of nervous fibers and neoplastic elements was seen in only one place, situated at the point of junction of the vestibular and acoustic fibers. Here certain fibers left the periphery to plunge directly into a loose reticular tissue where they were lost after a penetration of less than a millimeter (fig. 8). Because of the uncertainty of the results of the Bielschowsky and Cajal preparations, it was impossible to determine whether these fibers extended more deeply after losing their myelin sheaths.

3 For the study of the topographic distribution of the two sorts of tissue described, the tumor is divided into three parts of about equal volume; two sections, vertical and perpendicular to the greater axis divide the tumor into an internal portion, a middle portion and an external portion near the internal acoustic meatus.

Fig. 8.—Myelinated fibers plunging into the depth of the tumor; method of Loyer;  $\times 100$ .

In the internal portion thus delimited, there was a clear preponderance of fibrous tissue, which here formed vast areas separated by narrow bands of reticular tissue. In the median portion, the distribution was similar but less sharp; the fibrous nodules were more numerous in the inferior layers of this portion. Finally, in the lateral third of the tumor the distribution of the fibrous tissue was much more irregular; the small nodule of tumor extending into the internal acoustic meatus was formed of particularly dense fibrous zones.

This variable distribution of the two types of tissue apparently so different explains the variation in histologic appearance, and therefore the different terminology used for these tumors; a fragmentary examination must easily lead to errors in interpretation of the actual structure. In the case reported, a fragment taken from the superior portion of the

middle segment—which would have been the most accessible surgically—might be mistaken for a myxoid tumor; a piece of the internal segment of the same tumor would have an entirely different aspect because of the predominance of fibrous tissue and might be called a fibrogloma, and if the nuclei were numerous here the picture might suggest that of a sarcoma (gliosarcoma). Other analogous examples might be given.

It is clear from the foregoing remarks that the examination of fragments of tumors removed, for example, in the course of an operation may show a histologic aspect not corresponding in any way to the structure of the whole tumor.

The localization of the fibrous tissue, especially in the most internal portions of the tumor, may perhaps explain the fact noted by Dr. Cushing in the course of intracapsular enucleation of acoustic tumors, namely, that the portions most difficult to remove are generally situated in the neighborhood of the protuberance; they doubtless correspond to the numerous juxta pontile fibrous nodules encountered in the tumor described, as far as may be determined from a single case.

Is it possible to determine from which of the two branches of the acoustic nerve this neoplasm arose? In a schematic way it may be said that the tumor is included between the fibers of the cochlear branch behind and the vestibular branch forward (fig. 5 *B*); but, while the cochlear fibers are dissociated in such a way as to form by themselves a sort of shell for the tumor, the vestibular fibers remain grouped in a much more homogeneous formation. Moreover, it was found that the central end of the cochlear root showed much more marked degeneration than the vestibular. It seems, therefore, that the tumor arose rather from the cochlear division, although the volume of the tumor was too considerable to allow one to arrive at a certain solution of this question.

The evidence accumulated in recent years is in accord with the theory that the sheath cells of Schwann give origin to the tumors under discussion. During the course of the last century Bard, Gauthier, Grall, Durante and Klebs admitted an ectodermal origin, contrary to the reigning ideas of this time, but it was largely following the work of Verocay<sup>3</sup> that this theory was definitely established. Recently, Antoni<sup>4</sup> maintained that they arose from the supporting tissue of the nerves; Lhermitte and Leroux<sup>5</sup> arrived at the same conclusion and designated

---

4. Antoni, E.: Ueber Rückenmarkstumoren und Neurofibrome, Wiesbaden and Munich, 1920.

5. Lhermitte, J., and Leroux, R.: Étude histologique générale des gliomes des nerfs périphériques, des racines rachidiennes et des gliomes viscéraux, Rev. neurol., 1923, p. 286.

them "gliomes périphériques." Masson <sup>6</sup> is still more specific in introducing the term "Schwannome."

For these reasons, it would be interesting to determine at what point in the intracranial course of the nerve the tumor develops primitively: whether in its central portion in which neuroglial elements are found, or in its distal portion in which cells of Schwann are absent. Unfortunately, here again the volume of the tumor makes it impossible to determine the origin exactly. There is a distance of about 15 mm. between the apparent origin of the cochlear branch and its point of dispersion on the surface of the tumor, but one cannot base any certain conclusion on this observation, for the development of the tumor might have stretched the central root. Nevertheless, it makes one inclined to admit a peripheral point of origin; in the course of its growth the tumor would have progressed centrally, dissociating the fibers of the cochlear and later of the vestibular branch.

The disposition of the nervous fibers clearly gives the impression that they have been pushed to the periphery by a neoplasm which arose in the midst of them (fig. 5 B); they are intimately included, more or less according to the region examined, in the capsule of the tumor, but their interpenetration with the neoplastic tissue is infrequent and confined to the superficial layers—at least, as far as may be determined from the myelin sheaths. Recently, Ayala and Sabatucci <sup>7</sup> arrived at similar conclusions.

In order to establish the existence of a "neurogenic tissue," Verocay <sup>8</sup> insisted on the fact that the fibrous tissue did not give the usual tinctorial reactions of collogenic tissue. This fact has been verified many times since; the use of the aniline blue method of Mallory gave similar results. But the method of Perdrau shows in these areas a mass of fibrils, although their morphologic aspect, their number and their architectural disposition do not resemble in any way the pictures obtained by the same method with collogenic tissue. Moreover, one cannot be dealing here either with nervous fibers or with neuroglial fibers as one may convince oneself by the examination of the neighboring pons and bulb in which only the perivascular connective tissue is impregnated. The presence of a special fibrillary tissue in the fibrous areas seems to furnish another argument in favor of the existence of a peculiar tissue in these tumors. One should note that the method of Perdrau generally colors in black the precollogenic or reticular fibrils of the connective tissue.

7. Ayala, G., and Sabatucci, F.: *Klinischer und pathologischer Beitrag zum Studium der zentralen Neurofibromatosen*, *Ztschr. f. d. ges. Neurol. u. Psychiat.* 96:496, 1926.

In a case of acoustic tumor Derman<sup>8</sup> showed, by impregnation with Bielschowsky's method, delicate fibrils which continued into the perivascular connective tissue; if the impregnation was less intense, only the fibrils were colored. But the author did not identify these fibrils with nervous fibers with certainty. Nevertheless, in a tumor of the dura mater associated with cutaneous tumors, this author<sup>9</sup> found in the latter, besides the structure of a neurinoma of Verocay, fibrils impregnated by the method of Bielschowsky; for this reason, he seemed here to attribute to them a nervous nature. In a case of bilateral acoustic tumor accompanied by other nodules on the intracranial nerves, Hermann and Terplan<sup>10</sup> described fibers also, presumably nervous, disclosed by the same technic.

The procedure of Bielschowsky, at least in the tumor described in this paper, has not proved absolutely specific, as comparison with other methods showed. So I believe that one should be suspicious in these cases of fibers impregnated by this procedure. In the instances cited, they were probably precollogenic or reticular fibrils.

#### CONCLUSIONS

1. This study concerns an isolated tumor of the acoustic nerve probably developing from the distal portion of the cochlear division.

2. The fibers of the acoustic nerve spread out over the surface of the tumor; they penetrated it rarely and only superficially, if one may judge from the myelin sheaths.

3. Histologically, the tumor was formed of two tissues, reticular and fibrous, characteristic of acoustic tumors; their variable distribution in the tumor explains how the examination of a small fragment might lead to an erroneous histologic diagnosis.

4. This case verifies the operative observation of a juxtapontile localization of the denser parts of the tumor.

5. The method of Perdrau displays a special fibrillary formation which cannot be of either nervous or neuroglial nature.

# DIVERTICULUM OF THE BLADDER

## AN ANALYSIS OF THIRTY-ONE CASES \*

CHARLES TEEL

In a review of the cases of diverticulum of the urinary bladder observed in the urologic clinic of the Peter Bent Brigham Hospital, there are several points with which I have been especially impressed, perhaps, most of all by the frequent association of neoplasm and calculus of the bladder with diverticulum.

Thirty-one cases of diverticulum of the bladder were reviewed. In this group there was a sac of not less than 2 cm. in diameter in every case. In ten cases, or 30 per cent, there were multiple diverticula; in five others, the records mention the presence of additional cellules or saccules, varying in size up to 0.75 cm. in depth.

Diverticulum of the bladder is predominantly a disease of men. Only one case occurred in a woman, and this was not recognized before operation. In this case the sac was similar to those observed in men; it opened on the right lateral wall of the bladder, and was about one-third the size of the bladder, its wall being unusually thin.

Most of the patients had reached old age. More than one third of them were in the seventh decade of life, and only 20 per cent were less than 50 years of age.

Most of the diverticula were adjacent to the ureteric orifices; ten were near the right orifice, eight near the left. Most of these were described as having their openings just behind, and lateral to, the orifice. Four occurred in the midline behind the interureteric bar, six in the vault and one on each lateral wall.

Frequency of urination was the most common symptom. Difficulty in starting the stream, and burning and smarting on urination were also nearly always present, though often intermittent. Hematuria occurred in fifteen cases, or in practically half of the series; eight of these, however, were found to have an associated calculus or tumor of the bladder. In the other cases, the amount of bleeding was usually small. Seven patients, or 23 per cent, complained of pain, usually accompanying urination, varying from slight, dull suprapubic pain to terrific spasms in which the patient would sit in a chair and rock back and forth violently while voiding. In fifteen cases, the urine was cloudy and foul smelling; in eight there was a moderate to mild cystitis, and in the remaining seven, the urine was practically clear.

---

\* From the Peter Bent Brigham Hospital, Boston.

As to the duration of symptoms, only three patients told of urinary difficulty since childhood. The great majority of them had had symptoms for from one to seven years.

In most of the cases the kidneys functioned well, as judged by the output of phenolsulphonphthalein and the determinations of blood urea nitrogen. In only seven of the cases was the output of phthalein less than 30 per cent in two hours (intramuscular method). In one case, the patient entered the hospital with uremia; there was a gangrenous

Fig. 1.—The characteristic deformity of diverticulum. The lower shadow represents the cavity of the bladder. The rounded outline of a diverticulum appears just above.

cystitis, and pus could be seen exuding from both ureteral orifices. Unfortunately, autopsy was not performed.

The condition of the prostate gland in this group of cases is of special interest. Only four cases lacked evidence of hypertrophy of the gland or of contraction of the vesical orifice. Sometimes the prostatic enlargement was slight, but when this was the case, there was usually a definite contraction of the vesical orifice. In eighteen of the cases, or

58 per cent, the prostatic hypertrophy was described as marked. Eighteen of the twenty-four male patients (75 per cent) who came to operation underwent either enucleation of the prostate gland or excision of a median bar.

Perhaps the most interesting feature of this study was the frequent association of diverticulum with calculus, tumor, or both. Calculi of the bladder were present in eight of the thirty-one cases. In four of these, the calculus was found in the diverticulum; in the other four, it

Fig. 2.—Shadows of multiple diverticula. The outline of four sacs can be seen around the shadow of the bladder.

was free in the bladder. In one case, a stone, 6 cm. in diameter and weighing 93.5 Gm., was found in the diverticulum. Another case was unusual in that seven large stones, together weighing 107 Gm., lay directly on a carcinoma which involved nearly the whole floor of the bladder and part of the left lateral wall. There were also numerous prostatic calculi. The diverticulum opened in the vertex of the bladder.

A neoplasm of the bladder was present in seven cases. In three, the tumor appeared to originate from the lining of the diverticular sac, and

in each the growth was a papillary carcinoma. The tumor was entirely hidden within the diverticulum in one case, and was demonstrated only when the sac was excised at operation. In the other two cases, the growth completely filled the diverticulum, and protruded from its orifice in such a way that the presence of the sac was not suspected until excision of the tumor-bearing area of the wall was begun. It was then found that the tumor arose from the mucous membrane which lined a diverticulum.

In the other four cases, the growth did not involve the diverticulum. One patient had a papillary carcinoma involving the floor of the bladder; another had a colloid carcinoma; while two were cases of benign papilloma.

One of these cases seems worthy of special mention.

#### DIVERTICULUM WITH BENIGN PAPILLOMA

A carpenter, aged 60, had had attacks of chills and fever with urinary frequency for twenty years. The urine had been slightly cloudy, at times somewhat bloody. Examination revealed a large diverticulum with its orifice located on the right lateral wall of the bladder, just lateral to the right ureteral orifice. There were also two flat semisessile growths on the posterior wall of the bladder, apparently benign papillomas. At operation the diverticulum was excised. One tumor, which was removed for pathologic study, showed microscopically a structure typical of benign papilloma. The patient recovered from his operation, except for a somewhat persistent cystitis, and was discharged from the hospital. He was instructed to report to the outpatient department for observation and fulguration of the remaining papilloma. The patient did not return, however, and was not heard of, until eight years later, when he showed an extensive sloughing carcinoma of the bladder. He died a few months later.

The lesson to be learned from this case is, of course, that a benign growth should be regarded as at least potentially malignant, especially in the presence of infection which so frequently complicates these cases. Treatment should be given accordingly.

Twenty-five of the cases of this series came to operation. The usual method of excision was as follows: Preliminary drainage of the bladder was carried out, usually through a urethral retention catheter. A first stage cystostomy was avoided, as the resulting adhesions tend to form an even greater barrier to what is often a difficult dissection. When the condition of the patient had become satisfactory, the bladder was opened suprapubically and the diverticulum was packed with gauze. The adjacent pelvic tissues were then dissected from the outer wall of the bladder, in the region of the diverticulum. The sac itself was then defined, and narrowed down to its neck, which was cut through; the wall of the sac was removed, and the edges of the wall of the bladder were united with one or two rows of interrupted catgut.

If the sac is small and there has been little inflammatory reaction, it is sometimes possible to invert the entire wall of the diverticulum, as has been suggested by others, and, cutting across the neck, make the repair entirely from the bladder aspect. This is a much simpler process, as it eliminates the pelvic dissection. It was carried out in five cases of the series. It was not necessary in any case to dissect out the mucous membrane lining the diverticulum, leaving behind the rest of

Fig. 3.—A sac into which a ureteral catheter has been introduced through the cystoscope. This is a common method for bringing out the outline of the diverticulum more clearly.

the sac wall. Such a procedure is to be avoided; it is an exceptional case when this becomes necessary.

With a sufficiently long preoperative drainage of the bladder, it is sometimes possible to enucleate a small prostate at the same time that the diverticulum is excised. When there is any doubt about the condition of the patient, however, it is safer to carry out this procedure at another time.

Division and transplantation of a ureter to another part of the bladder was necessary in only three cases; two were cases of carcinoma, in which the growth was resected, and the ureteric orifice had to be sacrificed in order to allow a wide enough resection. In the third patient, the ureter emptied into the diverticulum, rather than into the cavity of the bladder. This was the only case in the series in which this situation was found.

Fig. 4—A fully distended bladder. Only a slight deformity is evident. Repeated roentgenograms are essential to accurate diagnosis

The difficulty of the operation depends primarily on two factors. The first is the extent of the surrounding pelvic adhesions. In cases in which infection has been especially severe and of long standing, adhesions become correspondingly firm and extensive, and the pelvic dissection consequently grows more difficult. The second factor is the location of the sac. While a diverticulum arising from the lateral walls or vertex usually proves relatively simple because of the ease with which satisfactory exposure is obtained, those growing from the more dependent parts of the bladder are much more difficult.

## DIVERTICULUM BELOW THE TRIGONE OF THE BLADDER

Illustrating such a condition was the case of W. P., a business manager, aged 41, who had had urinary difficulty as long as he could remember. This was characterized by periods of difficulty in starting the urinary stream, also by great urgency, frequency and pain on urination. Moderate pyuria was present. Nine years before he came to the Peter Bent Brigham Hospital, the patient had had a suprapubic cystotomy, and a calculus the size of an English walnut was removed. The diverticulum was recognized at that time, but apparently repair was not attempted. One

FIG. 5.—The same patient as in figure 4. When the bladder is partly emptied, the presence of the diverticulum is shown clearly.

year later, at one of the large urologic clinics, the diverticulum had been pronounced inoperable because of its location; nothing but excision of the median bar had been attempted. The symptoms continued, becoming even more severe during the next few years. The patient was incapacitated for days at a time. On entrance to the hospital, cystoscopy showed the orifice of a diverticulum, 15 cm. in diameter in the midline immediately behind the interureteric bar, while cystography showed the sac, the size of a lemon, passing downward so that practically the entire sac lay under the trigone of the bladder.

A midline suprapubic incision was made. Exposure was extremely difficult because of the scar tissue resulting from the two previous operations and long

continued infection. The neck of the sac was finally isolated, cut across, and the dissection of the diverticulum begun. The wall was thin and so closely incorporated with the wall of the rectum that it was only with the greatest care that the dissection was accomplished. The postoperative course was satisfactory; the patient was completely relieved of urgency and painful urination. There was some frequency due to a persistent cystitis, but after treatment for two months with frequent lavage of the bladder, this condition cleared up entirely. The patient has remained completely cured.

Relief from symptoms after operation in this series of cases was usually gratifying. The main postoperative difficulty was persistent cystitis which was often difficult to control, particularly in cases in which pyuria had been a marked symptom before operation. Six of the patients died within a year after operation, but four of these had carcinoma of the bladder, as already mentioned. One patient died from postoperative pulmonary embolism and one from bronchopneumonia.

Roentgenography has greatly simplified the diagnosis of diverticulum of the bladder. Many series of roentgenograms of the bladder have been published, and the technic has been adequately described. One point to be emphasized, which has been mentioned by others, is that the introduction of an opaque medium into the bladder, followed by a single negative roentgenogram, by no means rules out the presence of a diverticulum. The chief reason for this is shown by two roentgenograms of the same patient, reproduced herewith. The first, with the bladder well filled, shows little deformity, whereas the second, with the content of the bladder partly removed, shows the sac clearly outlined. Lateral views as well as anteroposterior ones should be taken, of course, to show the complete relations of the sac.

#### CONCLUSIONS

Diverticulum of the bladder is a condition in which a diagnosis is usually made without difficulty, by modern methods. Adequate treatment, consisting of complete excision of the sac with removal of any existing obstruction at the neck of the bladder and of residual infection, gives gratifying relief from symptoms which frequently have been of long standing and often almost unbearable.

# CONGENITAL ABSENCE OF THE VERMIFORM APPENDIX \*

J. I. BRADLEY

Congenital absence of the vermiform appendix is a rare anomaly. Its infrequency is illustrated by the following data: Of 8,102 cases examined in the autopsy and dissecting room, in which the presence or absence of the appendix was noted, only two showed congenital absence. The source of these figures is shown in table 1.

Further evidence of the rarity of the anomaly is found in the fact that, according to Dorland,<sup>1</sup> who reviewed the literature in 1925, only thirty-seven authentic cases have been reported. Other authors regard true cases of complete congenital absence as even more rare; thus, Dailey,<sup>2</sup> in 1910, accepted only ten of the twenty-six cases reported up to that time.

TABLE 1.—*Absence of Appendix in 8,102 Cases*

Authority	Number of Cases	Number Absent

7. Meckel, J. F.: Handbuch der path. Anat., Bd. I, 1912, p. 599.

a dissecting room subject. Since then thirteen additional cases have been reported from anatomic and pathologic laboratories.<sup>8</sup>

In addition, there are four specimens in museums: Two, referred to by Gladstone,<sup>9</sup> are at the Museum of the Royal College of Surgeons, England, and two, described by Huntington,<sup>10</sup> are at the Columbia University Museum. The occurrence of the anomaly is, therefore, well established.

In 1925, Dorland collected from the literature thirty-seven cases which he regarded as authentic. Schridde and Dailey are more critical and do not accept many of the earlier cases. A critical review has not been attempted; one case, however, which is reported by Shiels,<sup>11</sup> is considered dubious because of the extensive adhesions around the cecum.

In addition to the cases collected by Dorland, the literature contains references to four others, two of which have not actually been reported. Concerning one of the latter two cases<sup>12</sup> it was stated that at a meeting of the American Surgical Association in 1910, "Bloodgood signale un cas d'absence de l'appendice avec caecum situé très haut." Another report of this case cannot be found. The reference to the other case is made by Swan<sup>13</sup> who stated that Dr. Guiteras of Philadelphia, in a personal communication to him, reported seeing a case at autopsy at the Philadelphia General Hospital. Further reference to this case is lacking.

More definite is the report of a case demonstrated by Marie<sup>14</sup> before the Société Anatomique de Paris in 1903. The Bulletin of the society stated, "M. R. Marie montre un cecum dépourvu d'appendice iléo-caecal. Il n'y a pas trace de diverticule appendiculaire. La malformation est ici congénitale."

The fourth case is one recently reported by Maurer<sup>15</sup> in which an operation was undertaken for a diagnosis of appendicitis but an appendix was not found.

15. Maurer, Z.: *Rare Case of Absence of Appendix*, *Polska gaz. lek.* **6**:155, 1927.

Twelve of the thirty-seven cases reported by Dorland were surgical, that is, cases in which the appendix could not be found at operation. All these cases, it is realized, are open to criticism, for, from the nature of the circumstances, objections concerning the validity of the reports can be raised and cannot well be answered. The case which Dorland saw, in consultation after operation, is a pertinent demonstration of the fact that the observations at operation may be accurate, and provides a warning against too vigorous or prolonged a search. In this case, operation was undertaken with a diagnosis of appendicitis; a search of forty-five minutes failed to reveal the appendix; the patient died three days later of postoperative ileus; autopsy confirmed the operative observations. The possibility of the appendix lying in an unusual position, however, in which it cannot be discovered by safe search will always render surgical reports somewhat dubious. The warning given by Dailey, that "one should not be too hasty in publishing alleged cases of absent appendix for there are many possibilities of error" is justified. Nevertheless, it seems reasonable to accept, tentatively, cases lacking evidence either of previous surgical intervention or of any pathologic process which may have destroyed the organ and in which a careful search is unsuccessful. Such is the case presented here.

#### REPORT OF CASE

*History.*—A West Indian man, unmarried and 19 years of age, was referred to the hospital by his family physician with a diagnosis of "mild acute appendicitis." The history was essentially negative; it did not include previous attacks of abdominal pain or operations.

*Present Illness.*—Two weeks prior to admission the patient first complained of nausea and diffuse abdominal distress which lasted all day. A feeling of abdominal discomfort persisted during the next two weeks. On three occasions he complained of dull, diffuse lower abdominal pain, more marked in the right lower quadrant. The patient was seen in the outdoor department six days before admission; examination showed slight tenderness in the right lower quadrant, a temperature of 99.6 F. and a white blood count of 14,900. Admission to the hospital with a diagnosis of appendicitis was advised but refused by the patient who was, however, referred to the hospital by his local physician six days later, with the same diagnosis.

*Physical Examination.*—A general examination gave negative results. Except for slight tenderness on deep palpation over McBurney's point, without spasm, the abdomen appeared normal. Scars were not present. The temperature was 98 F.; the white cell count, 10,700. Tests of the urine gave negative results. The Wassermann reaction of the blood was negative. A roentgenogram of the urinary tract did not show evidence of calculi. The case gave the appearance of a subsiding appendicitis.

*Operation.*—On opening the peritoneum, the cecum was found exposed in the wound. Digital exploration did not disclose the appendix. The cecum was drawn up into the wound until its lower end and the ileocecal junction were exposed; the teniae coli were identified, followed to their terminations and found to end in a small, mound-like, conical elevation about 1 cm. in diameter and 3 mm. in height. The lower end of the cecum, the pericecal and retrocecal regions were

explored but nothing else resembling an appendix could be found. The cecum was rather mobile and of normal size; the walls in the lower portion were possibly slightly thickened but did not disclose injection or inflammation. There were a number of lymph nodes from 2 to 5 mm. in diameter, of normal color and consistence over the lower end of the cecum and in the adjacent mesentery. The examination was repeated by the assistant resident surgeon, by the resident surgeon and by the visiting surgeon, with confirmation of the foregoing observations. The convalescence was uneventful.

Of especial interest is the embryologic explanation of the anomaly. According to Kelly and Hurdon,<sup>16</sup> the appendix is "merely a portion of the general cecal pouch which has remained in an early stage of development." It is formed from the terminal portion of the cecal pouch from which it is at first indistinguishable. Differentiation takes place in two stages: A primary stage occurs at about eight weeks when a distinction can first be made between a larger proximal portion (cecum) and a smaller distal portion (appendix). A secondary stage occurs at about the time of birth, coincident with the formation of the teniae, when a more marked disproportion between the size of the cecum and that of the appendix becomes evident. Development may be interfered with at any stage. The resultant anomalies have been postulated as follows:

TABLE 2—*The Arrested Development of the Cecal Pouch and the Resultant Anomalies*

Stage of Growth	Anomaly
Failure of the cecal anlage to develop	Absence of the cecum and appendix
Partial development of the cecal anlage	Rudimentary cecum without the appendix
Full development of the cecal portion; no development of the appendiceal portion	Normal cecum; no appendix
Normal early differentiation of the appendix, but early discontinuance of development	Normal cecum; rudimentary appendix
Normal early development but failure of appendiceal portion to become differentiated, its growth keeping pace with that of the cecal portion so that a differentiation is not evident	Normal appearing cecum probably with extra banstra, as in case reported by Schnidde; no appendix

The small conical elevation at the junction of the teniae in the case described is interpreted to represent a rudimentary appendix. This case may be regarded, therefore, as representing the fourth possibility and should probably be classed as a hypoplasia rather than a true aplasia. In the case reported by Marshall and Edwards,<sup>17</sup> however, which is generally accepted as one of true congenital absence or aplasia, there was a papular elevation 2 mm. high at the junction of the longitudinal bands, while on the mucosal side there was a shallow depression corresponding to the orifice of the appendix.

16 Kelly, H. A., and Hurdon, E.: *The Vermiform Appendix*, Philadelphia, W. B. Saunders Company, 1905.

17. Marshall, H. T., and Edwards, R. T. (footnote 8; fifth reference).

## SUMMARY

A case of congenital absence or of hypoplasia of the vermiform appendix, observed at operation, is reported.

Two other cases, one demonstrated by Marie in 1903 and one reported by Maurer in 1927, are added to the thirty-seven cases collected previously.

The anomaly is rare, the total number of recognized cases not exceeding forty.

# CONGENITAL COXA VARA\*

JOSEPH S. BARR

The purpose of this paper is to review briefly the literature and to report five additional cases of what is referred to by various writers as congenital, infantile or cervical coxa vara. Coxa vara is an anatomic term now used to indicate a diminution from normal of the angle between the neck and the shaft of the femur.

Since coxa vara is caused by the strain of weight-bearing on a weakened femoral neck, one finds that the cases fall into certain groups, depending on the etiology of the weakness. A classification now generally used is as follows:

1. Congenital coxa vara (the infantile or cervical type of Elmslie and Fairbanks).

2. Acquired coxa vara.

- (a) Due to local pathologic processes such as cervical fracture, tuberculous or pyogenic infection, metastatic malignancy and similar conditions.

- (b) Adolescent coxa vara, which Noble and Hauser believe is due to pituitary dysfunction.

- (c) Coxa vara due to generalized disease of bone, such as rickets, osteitis deformans and other conditions.

Congenital coxa vara, as Jones and Lovett stated in their textbook, "has not been sufficiently emphasized and is of importance as an entity." It was first recognized by Krebel in 1896 when he reported two cases, but he had neither x-ray nor pathologic evidence to support his diagnosis. Hoffa, in 1905, described two cases of undoubted congenital coxa vara, and supported the diagnosis by a resected specimen from one and by roentgenograms of both cases. Since that time the literature on the subject has increased rapidly and is now voluminous. The more important articles are listed in the appended bibliography.

## CLINICAL FEATURES

Symptoms are noticed at any time from the beginning of weight-bearing until the age of 6 or 8 years. The onset is insidious; usually there is a painless limp which becomes slowly but progressively worse. Slight trauma, insignificant ordinarily, may cause exacerbation of symptoms. Pain in the region of the affected hip is present in a considerable percentage of the cases but usually occurs late, apparently due to postural changes. Both sexes are equally affected. About 30 per cent of the cases are bilateral. Fairbanks asserted that the left hip is more commonly affected than the right but quoted no statistics in support of the statement.

---

\* From the Orthopedic Service of the Children's Hospital, Boston.

On physical examination, the leg is found to be short; abduction is markedly limited, and there may be some limitation in the extremes of extension and internal rotation. Passive motion within the limits allowed is usually painless. If the coxa vara is marked Trendelenberg's sign may be present. The trochanter is always above Nélaton's line. In bilateral cases the gait is waddling, and lordosis may be marked, simulating closely congenital dislocation of the hips, but there is no "piston mobility" present. The gait in unilateral cases is usually that of a simple short leg limp. An interesting feature is the frequent association of other congenital defects. Fairbanks reported three cases in which craniocleidodysostosis, that is, deficient ossification of the clavicles and parietal bones, was present. A careful search should be made in every case for other congenital defects.

Roentgen examination is characteristic and, with the clinical evidence, makes the diagnosis relatively simple. There is a defect in ossification of the femoral neck, which usually appears in the film as a clear, vertical band extending through the whole neck, resembling to some extent an old fracture, ununited. The band may take the appearance of an inverted V or Y, enclosing a triangular piece of bone which is apparently separate from the rest of the neck. The trochanter is high and may impinge on the ilium. There is increasing deformity as the head is driven downward. The neck becomes shorter, and later it may be completely absent, the head fusing to the shaft at the level of the lesser trochanter.

#### PATHOLOGIC ANATOMY

The pathologic changes in congenital coxa vara are not so clearly defined as one might desire, due chiefly to the lack of material. The resected specimens of Hoffa and Jones were both from adults, and the histology was not carefully studied. At operation a fissure corresponding to the line seen in the x-ray picture is found. This break in continuity of bone is not a space but is filled with "non-calcified osteoid tissue" (Noble and Hauser). They published a photomicrograph which showed "irregularity of the epiphysis with islands of cartilage lying in the spongiosa and areas of osteoid tissue in the epiphysis."

Among the cases here reported, only one patient was operated on. The material removed from the midcervical region was subjected to microscopic examination by Dr. S. B. Wolfbach. The pathologist's description follows:

"Six sections were made of the fragment of tissue received, which were composed of bone cartilage, fibrous tissue and muscle. Portions of the bony fragments showed the usual bone spicules and bone marrow. In three sections there was an alteration in the histology from that found in normal bone. The cartilaginous junction with the bone spicules was rather abrupt. The cartilage cells did not assume the linear

arrangement nor the enlargement usually found along the line of ossification. The invasion of cartilage by blood capillaries was entirely absent. The marrow space in these sections ended abruptly at its junction with the cartilage. Cartilage was similar in appearance to that found in the articular surface. The cartilage in one area was found to be intimately united with bone spicules rather deep in the spongy bone. Islands of disintegrated cartilage were also found between the bone spicules. Some of the spicules showed evidence of faulty laying down of bone matrix and some atrophy of bone. Nowhere was there marked evidence of bone formation, nor was there evidence of repair. Owing to the fragmentary character of the tissue, the exact relation of this cartilage to the surrounding bone could not be determined. The histology was not sufficiently characteristic to permit a definite diagnosis as to the cause of the bony change. Somewhat similar changes are sometimes found in bones of animals in which there is a vitamin deficiency, other than those which are known to influence the laying down of normal bone."

Schwarz was the first writer to advance the theory that the fissure seen in the x-ray picture is a portion of the embryonic neck disk which has not been replaced by bone. The bone itself is normal so far as can be determined. The pathologic changes in this case (case 1) are in accord with this theory. Uterine malposition and abnormal vascularization of the neck have been suggested as causes of the deficiency in ossification. The evidence in favor of either is inconclusive.

#### TREATMENT

Practically all writers agree that untreated congenital coxa vara tends to run a progressive course with increasing deformity and disability. Fairbanks recommended subtrochanteric osteotomy to improve the weight-bearing line. He reported having operated on nine patients by this method with satisfactory results in eight. Noble and Hauser stated that such an operation is only of temporary benefit and recommended either a plastic operation on the head and neck after Brackett's method or the bifurcating operation of Lorenz. Brackett's operation, originally designed for ununited fracture of the femoral neck, consists in fixing the head and upper portion of the neck, divided by osteotomy, on the end of the femur and moving the greater trochanter further down on the shaft. Lovett and Jones suggested prolonged immobilization in an abduction splint without weight-bearing. The patients in the cases here reported have, with one exception, been treated nonoperatively. The final outcome is subjudice as all of the patients are still under treatment.

It seems probable that treatment should be conservative until puberty, relying on abduction, nonweight-bearing and manipulation to keep the

deformity from increasing. If this fails, then Brackett's operation would seem to be the method of choice, for it gives less shortening and replaces the weight-bearing lines better than subtrochanteric osteotomy or Lorenz' operation. Osteotomy through the neck of the femur is inadvisable because of the danger of nonunion.

#### REPORT OF CASES

CASE 1.—R. L., a boy, aged 10, at the time of first admission, entered the hospital on Aug. 25, 1927, complaining of pain and stiffness in the right hip. The family and past histories were essentially negative. Since the age of 2, the child had had intermittent pain and stiffness in the right hip accompanied by a limp. Occasionally the child was confined to bed because of the pain. For three days

Fig. 1 (case 1).—The condition of the hip on Aug. 25, 1927.

before admission the pain in the hip had been severe. He had no treatment previous to the time he entered the hospital.

Results of physical examination were negative except for the local condition. All motions of the right leg were limited by spasm of the muscles about the hip. The right leg was  $1\frac{1}{4}$  inches shorter than the left. The child walked with a right short leg limp, tilting the pelvis to the opposite side. The Wassermann test was negative. An intradermal tuberculin test (1:1,000) was positive. Roentgen examination revealed an apparent fissure through the neck of the femur with moderate coxa vara (fig. 1).

Manipulation under ether failed to change the position of the neck, and so, on Sept. 16, 1927, with the patient under ether anesthesia a wedge osteotomy of the neck was done through a posterior (Ober) incision. The pathologic report on the fragments removed has already been given. The leg was immobilized in a plaster spica in full abduction. Convalescence was smooth, but the position of the proximal fragment was not entirely satisfactory. Traction and a second manipulation failed to change the position. After six months of immobilization, weight-bearing in an abduction splint was begun. At the present time the patient is on unrestricted

activity and has no pain or discomfort. Examination on Sept. 30, 1928, revealed the right leg to be  $1\frac{3}{4}$  inches shorter than the left. No motion was demonstrable in the hip which was held in 30 degrees flexion. The child walked well, was free from pain, and his father considered him to be much improved. An x-ray picture showed the trochanter impinging on the ilium (fig. 2). The apparent ankylosis is due to this extra-articular bony contact, and a plastic operation by Brackett's method seems to be indicated in this case.

CASE 2.—G. H., a boy, aged 2 years and 8 months, entered the hospital on Aug. 12, 1927. The family history was negative. The patient, of the eleventh pregnancy, was born at full term, with a normal delivery. A meningocoele through a spina bifida was noticed at birth and was closed by a plastic operation at the Children's Hospital when the patient was 6 weeks of age. Recovery was uneventful, and he was apparently entirely well until he began to walk, at the age of 15

Fig. 2 (case 1).—X-ray picture taken on Sept. 30, 1928.

months. At that time, or shortly thereafter, his gait was noticed to be unsightly. The deformity continued to increase, without pain or discomfort, and he was brought to the hospital for study. Physical examination revealed nothing of note except a spina bifida and the local condition.

The child stood with moderate lordosis, prominent abdomen and buttocks. The trochanters were prominent and above Nélaton's line. Trendelenburg's sign was positive bilaterally. The legs were of equal length, well developed and symmetrical. Passive motions were normal except for limitation of internal rotation on both sides and limitation of abduction on the right. He walked with a waddling gait slightly resembling that of bilateral congenital dislocated hips. The Wassermann and tuberculin tests were negative. Roentgen examination revealed defective ossification of both femoral necks, which was more marked on the left.

After manipulation under ether anesthesia in the direction of abduction, the legs were immobilized in a plaster spica for a period of ten weeks. Weight-bearing was begun shortly thereafter, and at the present time the patient is unrestricted in activity. When seen last, on Sept. 30, 1928, there had been little change in the condition. He complained of no discomfort. The coxa vara had not increased. Figure 3 shows the x-ray picture at that time.

CASE 3.—P. H., a girl, aged 4 years and 10 months, entered the hospital on Oct. 18, 1926. The family and past histories were negative. When the patient was  $3\frac{1}{2}$  years of age, the mother first noticed a right leg limp. There was no history of trauma. The limp increased steadily, without pain, until shortly before entry when some discomfort was first noted. This increased steadily until at entry the child could scarcely bear weight on the right leg.

Examination revealed shortening of the right leg amounting to three fourths of an inch with all motions of the right hip restricted to about 10 degrees by muscle spasm. The x-ray picture was typical of congenital coxa vara, showing the triangular piece of bone separate from the rest of the neck which is stressed by Fairbanks as being so characteristic (fig. 4). Treatment consisted in immobilization, with the leg in 10 degrees abduction, in a plaster spica for a period of six months. The child was then gradually allowed on her feet. She was last seen in the outpatient department on Aug. 10, 1928. She was having no pain or

Fig. 3 (case 2).—X-ray picture taken on Sept. 30, 1928. The picture is essentially the same as that at the time of entry.

discomfort and walked almost perfectly with a one-fourth inch cork insert in the right heel. Abduction was limited to 15 degrees; the other motions of the hip were practically normal. There was a slight functional right total scoliosis. Figure 5 shows that ossification is progressing and that the defect is disappearing. This patient seems to be doing excellently under conservative treatment.

CASE 4.—L. D., a girl, aged 10 years, entered the ward for the first time on Jan. 4, 1927. The family history was negative. A clavicle was fractured at birth but healed without difficulty. The child began to walk at the age of 1 year, and shortly thereafter the mother noted a left leg limp. There was no history of trauma or pain. The mother brought the child to the outpatient department on June 11, 1919, when the patient was  $2\frac{1}{2}$  years old. A diagnosis of "Rickets with coxa vara" was made, but no x-ray picture was taken. She was not seen again until Dec. 29, 1926, when she returned to the outpatient department. The mother stated that the limp improved after her first visit until December, 1925, when the

Fig. 4 (case 3).—X-ray picture taken on April 26, 1927. The triangular piece of bone, apparently separate from the neck, should be noted.

Fig. 5 (case 3).—X-ray picture taken on May 11, 1928, showing ossification taking place. Compare with figure 4.

patient sustained a fall on the ice. She was kept in bed for one day. The left leg limp increased steadily from that time on. The patient was admitted for study and treatment of a painless but unsightly limp.

Physical examination revealed normal motion of the hips with the exception of slight limitation of abduction and lack of hyperextension of the left hip. The left leg was  $1\frac{1}{4}$  inches shorter than the right. The tuberculin and Wassermann tests were negative. The x-ray picture showed an irregular bony defect extending through the neck of the left femur (fig. 6). Without the history of a limp beginning in infancy the history of trauma would suggest that this was a case of mal-united fracture of the femoral neck. As shown by René Bloeh, however, fracture of the neck of femur during childhood is an extremely rare condition and requires crushing violence to produce it. In this case the trauma, imposed on a poorly ossified femoral neck, was apparently sufficient to cause an exacerbation of symptoms.

Fig. 6 (case 4).—Appearance of hips on Dec. 29, 1926.

The leg was immobilized in a plaster spica in 25 degrees abduction for seven months. The x-ray picture taken at the end of that time showed that ossification was proceeding satisfactorily (fig. 7). The child is now on unrestricted activity. When last seen in the outpatient department in January, 1928, she had no symptoms except a slight limp, corrected almost completely by a raise on the left shoe. There was 2 inches of shortening of the left leg.

CASE 5.—M. L., a girl, aged 4 years, at the time of admission, entered the hospital on May 28, 1924. The family and past histories were negative. Since the patient began to walk at the age of 26 months, an abnormal waddling gait had been noticed. Physical examination on admission showed short arms and legs, lumbar lordosis, trochanters high, hips limited in abduction and a waddling gait. She was considered a dwarf, probably achondroplasic in type. During the following three years, between the ages of 4 and 7, she grew only 3 inches in height. Extensive laboratory study on several entries gave negative results. This included determination of blood calcium and phosphorus, basal metabolic rate and other tests. Roentgen study of the entire skeleton revealed no abnormalities except of the hips,

Fig. 7 (case 4)—The filling in of the bony defect after seven months' immobilization; taken on Aug 11, 1927.

Fig 8 (case 5).—X-ray picture taken on Dec. 15, 1921, when the child was 27 months old. Note that the center of ossification of the femoral heads, which normally appears at the end of the first year, is absent; also the nutritional disturbance lines at the distal end of the femoral diaphyses.

which showed the typical picture of congenital coxa vara. Figure 8 shows a plate of the pelvis taken at the age of 27 months. Figure 9 shows the condition of the hips at the present time, at the age of 8½ years. In this case also the triangular piece of bone is present on the left but not on the right. Treatment so far has consisted in limitation of weight-bearing and a general hygienic regimen.

#### CONCLUSIONS

Congenital coxa vara is a distinct clinical entity which occurs with sufficient frequency to make its recognition in any diagnostic clinic a real necessity.

The diagnosis rests on clinical and x-ray evidence and is comparatively easy to make. A painless limp, either unilateral or bilateral occurring soon after the subject has begun to walk, is the usual his-

Fig. 9 (case 5).—X-ray picture taken on Sept. 7, 1928.

tory. Examination reveals the trochanter to be high; the leg is short, abduction is limited and piston mobility is absent. The x-ray picture shows a defect in ossification of the femoral neck resembling a fracture without displacement.

The pathologic process is not entirely clear, but apparently there is a defect in ossification of the femoral neck with the inclusion of a disk of embryonic cartilage in normal bone.

The condition in untreated patients runs a progressive course with increasing disability. Early treatment should consist in immobilization of the hip in full abduction. Later, if marked deformity occurs, a plastic operation after Brackett's method seems to be the procedure of choice.

# THE EFFECT OF SOME ANTISEPTICS ON TISSUES IN VITRO \*

WILLIAM J. GERMAN

A great deal of work has been done within the last few years on the bactericidal effects of various antiseptics. A search of the literature, however, reveals little regarding the effects of these substances on living tissue. The criterion by which the efficacy of an antiseptic may be judged is twofold. Its bactericidal effect should be high, and at the same time it should have no injurious effect on the tissues to which it is applied. It is obvious that substances which are general protoplasmic poisons cannot fulfil the requirements for a perfect antiseptic. Many of these, however, have been used and have undoubtedly played an important part as a cause of delay in the healing of wounds. The perfect antiseptic should therefore have a specific action on bacteria, and be capable of acting efficiently in the presence of serum.

The purpose of the present work is merely to develop a method by which the action of antiseptics on living tissues may be conveniently studied, and to state the effects produced by some of the more commonly used antiseptics. In selecting the antiseptics to be tested, an attempt was made to choose only those which had been proved to be efficient germicides.

Since its introduction by Grossich<sup>1</sup> in 1908, the use of iodine in the sterilization of the skin has been extremely popular. That the results obtained have not justified its popularity is clearly illustrated in Tinker's<sup>2</sup> review of the subject, which shows the frequent presence of infection after the application of iodine. The average incidence of bacterial growth after the use of iodine was 25 per cent for skin scrapings and 40 per cent for excised skin, indicating a low penetrative and also a low bactericidal power.

The difficulty of determining the actual efficiency of antiseptics, when used on the skin, may be appreciated in the light of Tinker and Sutton's<sup>3</sup> observation that skin scrapings from protected regions showed no bacterial growth in from 20 to 25 per cent of the cases tested, in the absence of any preparation. The same observers found that a simple

scrubbing with soap and water for two minutes reduced the percentage of growth to 70 per cent, while the usual surgical preparation with soap and water, ether, alcohol and 1:1,000 mercuric chloride resulted in growth in but 25 per cent. It is obvious, therefore, that any antiseptic giving an incidence of bacterial growth greater than 25 per cent could hardly be considered efficient.

Churchman,<sup>4</sup> while studying the selective bacteriostatic action of gentian violet, found that most of the gram-positive organisms failed to grow in a medium containing a 1:100,000 concentration of the dye, while gram-negative organisms were usually not affected. In a later paper, Churchman<sup>5</sup> stated that acriflavine had an opposite selectivity, acting on the gram-negative organisms. A mixture of the two dyes appeared to be as efficient as either alone.

Testing the antiseptic action of iodine, picric acid, Harrington's solution, mercurochrome-220 soluble, acriflavine and acriviolet, on infected strips of rubber, Tinker and Sutton<sup>2</sup> found that the growth of all the organisms tested, except anthrax spores, was inhibited by acriflavine. All the other antiseptics showed a considerably higher percentage of bacterial growth. Furthermore, Browning and Gilmour<sup>6</sup> have pointed out that the antiseptic action of acriflavine is enhanced by the presence of serum. Browning, Gulbransen and Thornton,<sup>7</sup> however, found that two hours were required for sterilization of a very dilute suspension of *Bacillus coli* and *Staphylococcus aureus* in serum, by acriflavine 1:20,000. Using a more concentrated suspension of *Staphylococcus aureus*, Dakin and Dunham<sup>8</sup> found the lethal concentration of acriflavine to be between 1:3,000 and 1:10,000 in serum or blood, and that twenty-four hours were required for sterilization. It is obvious, therefore, that the antiseptic action of acriflavine is rather slow.

The bactericidal action of potassium mercuric iodide was pointed out by MacFarlan,<sup>9</sup> who found that a concentration of 1:5,000 killed

*B. coli* in ten minutes, while 1:1,000 was effective on *Bacillus subtilis* in twenty-four hours, and 1:500 on *Staphylococcus* in six hours. Watson<sup>10</sup> found a dilution of 1:80,000 efficient in killing *Bacillus typhosus* and *Staphylococcus* in twenty-four hours. A 1 per cent solution, however, was found to be irritating to the skin, especially to the mucous membrane.

Using a 2 per cent solution of mercurochrome in acetone and alcohol, Scott and Hill<sup>11</sup> were able to kill *Staphylococcus aureus*, *Bacillus coli*, and *Bacillus proteus* in one minute. In a later paper,<sup>12</sup> they said they found that the same solution was bactericidal for vegetative *Bacillus anthracis* and *Bacillus pyocyaneus* in one minute.

Picric acid has been used rather widely as an antiseptic for the skin, although the observations of Tinker and Sutton<sup>3</sup> would indicate it to be less effective than acriflavine or mercurochrome.

In the present work, gentian violet, acriflavine, potassium mercuric iodide, mercurochrome and picric acid were selected for the determination of their effect on living tissue.

Regarding the effect of antiseptics on tissues, Russell<sup>13</sup> showed that gentian violet was lethal to paramacia in concentrations greater than 1:500,000, while the endothelium of adult frogs showed growth in concentrations up to 1:2,000. The epithelium and mesenchyme of embryonic frogs were able to grow in the presence of gentian violet 1:4,000.

Bond<sup>14</sup> and Browning, Gulbransen and Thornton<sup>7</sup> found that the phagocytic power of leukocytes was not destroyed by acriflavine 1:1,000. Scott and Hill<sup>11</sup> injected 20 minims (1.25 cc.) each of 3.5 per cent iodine in alcohol, 1 per cent potassium mercuric iodide in acetone, 5 per cent picric acid in alcohol, and 2 per cent mercurochrome in acetone and alcohol, into the skin of rabbits and found that the areas receiving injections of the last mentioned solution always healed as soon and in many instances sooner than those given injections of the other preparations.

## METHOD OF EXPERIMENT

Tissue cultures of the skin of chicken embryos, from six to nine days old, were used to test the effect of the antiseptics on tissue. Bits of the embryonic skin were allowed to remain in various dilutions of the antiseptics for periods of one and five minutes. They were then washed in Locke's solution and mounted in hanging drop preparations according to the method of Lewis and Lewis.<sup>15</sup> The mediums used for the tissue cultures consisted of equal parts of coagulated chicken plasma, embryonic extract and Locke's solution. The cultures were then placed in an incubator at 37.5 C. and observed every day for five days. Control cultures of normal skin were made in each experiment.

The criterion adopted for determining the viability of the cultures was the migration of the cells from the explant.

The antiseptics were dissolved in Locke's solution. The dilutions used were 1:50, 1:100, 1:200, 1:400, 1:800 and 1:1,600 for mercurochrome, picric acid and potassium mercuric iodide; and 1:400, 1:800, 1:1,600, 1:3,200 and 1:6,400 for acriflavine and gentian violet. The solutions of the last two substances were more dilute on account of their relatively low solubility.

The bacteriostatic effect of the same dilutions of these antiseptics was also determined for *Streptococcus hemolyticus*, *Staphylococcus aureus* and *B. coli*. In these determinations, small bits of muscle and fascia were used as a medium of transfer for the organisms, in an effort to simulate the conditions under which the antiseptics would be required to exert their effect in the sterilization of wounds. The bits of muscle and fascia were placed in pure undiluted broth cultures of the organisms and then transferred to the antiseptic solutions. After periods of one and five minutes they were removed and planted on agar plates, the tissue being allowed to remain on the surface of the agar. The bacteriostatic action of the antiseptic remaining on the tissue was thereby allowed to exert its effect. The plates were examined for growth at the end of twenty-four and forty-eight hours. Control cultures were made by transferring the organisms to agar plates in the same manner, but without previous immersion in the antiseptic solutions. The cultures were kept at 37.5 C.

## RESULTS

All the normal tissue culture controls, numbering about fifty, showed definite migration of cells at the end of twenty-four hours. This continued throughout the period of observation, consisting of five days. The proliferation of the fibroblasts was most marked, but the epithelial cells showed some migration. In every case, the migration of the cells in the control specimens was more extensive than in the cultures subjected to the antiseptic solutions. Many of the test cultures, however, showed definite migration of cells, although this was usually later in appearing than in the controls, being apparent only on the third day in the case of the cultures subjected to mercurochrome. Most of the cultures in which cell migration occurred showed the same cellular type of proliferation as that observed in the control cultures. Acriflavine, however, seemed to exert an inhibiting effect on the fibroblasts, the epithelial proliferation appearing more distinct in this case.

15. Lewis, M. R., and Lewis, W. H.: The Growth of Embryonic Chick Tissues in Artificial Media, Agar and Bouillon, Bull. Johns Hopkins Hosp. 22:126, 1911.

Gentian violet exhibited this effect, though to a lesser degree. This phenomenon was previously noted in the case of gentian violet by Russell,<sup>13</sup> who found that the endothelium of frogs grew better than fibroblasts in the presence of this dye. In all, about ten cultures were made

in each dilution of the antiseptics tested. The percentage of cultures showing cell migration in the various dilutions of the antiseptics is illustrated in table 1.

The percentage of bacterial cultures showing growth is illustrated in table 2.

A comparison of these two tables reveals the fact that the only antiseptics exerting a bactericidal effect in dilutions compatible with tissue viability, according to this method, are gentian violet, picric acid and acriflavine. Of these, the last named is apparently by far the most selective in its action on bacteria.

Since the efficiency of an antiseptic must be in direct proportion to its bacteriostatic effect and in inverse proportion to its harmful action on the tissues, it is possible to calculate, from the data at hand, the efficiency of the antiseptics used. In other words, the efficiency varies directly with the bacteriostatic effect and the viability, or lack of damage to the tissues. An ideal antiseptic, therefore, would have a bacteriostatic effect of 100 per cent and a tissue viability of 100 per cent. The product of these two values would give an index of efficiency of one ( $1.00 \times 1.00 = 1$ ). Taking the average values, both in the case of the different bacteria and for the periods of one and five minutes,

TABLE 3.—*Indexes of Efficiency of Various Antiseptics*

	Gentian Violet	Acriflavine	Potassium Mercuric Iodide	Mercurio- chrome	Picric Acid
1:50	...	...	0	0	0.0975
1:100	...	...	0	0	0.0132
1:200	...	...	0	0	0
1:400	0	0.0684	0	0.0132	0
1:800	0	0.1914	0	0.006	0
1:1600	0.03	0.1540	0	0.0125	0
1:3200	0	0.088			
1:6400	0	0.0435			

of the bacteriostatic and tissue viability functions of the antiseptics studied, the indexes of efficiency have been calculated and are shown in table 3.

Obviously, this is a severe test for any antiseptic. Potassium mercuric iodide, for instance, in spite of its apparently good bacteriostatic action, scored zero throughout because of the fact that the tissue cultures exposed to it showed no evidence of viability. Conversely, the index of efficiency of picric acid was low, in spite of relatively good tissue viability, since its bacteriostatic power appeared rather poor. On the other hand, acriflavine showed relatively good results, especially in dilutions of 1:800 and 1:1,600 owing to its fairly good bacteriostatic effect and tissue viability.

The results shown in table 3, as a whole, were rather disappointing so far as the indication of an efficient antiseptic was concerned. However, they serve to show how far from perfect are the antiseptics in use.

Of course, before any final index of efficiency can be determined, the effects of the antiseptics on a great many more bacterial organisms must be investigated. Even then there can be only a rough estimate

of efficiency, since the variability of experimental results in this field is quite notorious. However, it is at least a gesture toward the preservation of viability of tissues in the use of antiseptics.

#### SUMMARY AND CONCLUSIONS

1. A study of the effects of certain antiseptics on living tissues has been undertaken. The antiseptics used were gentian violet, acriflavine, potassium mercuric iodide, mercurochrome and picric acid.

2. The effect of these antiseptics was determined on tissue cultures of the skin of embryonic chicks. Dilutions of the antiseptics of from 1:50 to 1:6,400 were used, the tissues being immersed in these for periods of one and five minutes.

3. A parallel series of determinations was made on the effect of the same dilutions of the antiseptics on *Staphylococcus aureus*, *Streptococcus hemolyticus* and *B. coli*.

4. From the data obtained in these two determinations, an index of efficiency was calculated for each dilution of the various antiseptics. This was derived by multiplying the bacteriostatic effect by the percentage of viability of the tissue cultures.

5. The highest values for tissue viability were obtained with acriflavine. This antiseptic also showed the greatest bacteriostatic effect for high dilutions. For low dilutions, the highest bacteriostatic effect was obtained with potassium mercuric iodide, but this substance gave a tissue viability of zero throughout the determinations.

6. Calculated on the basis of 1 for a perfect antiseptic, that is, having a bacteriocidal value and a tissue viability each of 100 per cent, the maximum indexes of efficiency for the different antiseptics tested were: gentian violet 0.03; acriflavine 0.1914; potassium mercuric iodide 0; mercurochrome 0.0132, and picric acid 0.0975.

7. The highest efficiency of acriflavine was found in dilutions of from 1:800 to 1:1,600.

# THE OPERATIVE MORTALITY IN A SERIES OF INTRACRANIAL TUMORS\*

LOUISE EISENHARDT

It is the purpose of this paper to give the computed mortality percentages for the operations on patients with intracranial tumors in the Peter Bent Brigham Hospital. In order to have information available regarding the number of tumors of different kinds in different locations, special care has been taken for several years to keep track of the patients after they have passed through the clinic. Such detailed statistics as are needed from day to day can hardly be supplied by the record room of the hospital where the clinical histories are officially filed and indexed. The number of cases, as a matter of fact, has become so large that some such system is necessary if the figures are to be kept constantly up to date, because of the frequent changes in diagnosis as new information regarding obscure cases is obtained by secondary operations, here or elsewhere, or by postmortem examinations.

As an aid in the interpretation of the first seven tables, a brief explanation of the terms customarily used in the primary subdivision of all cases referred to the hospital because of existent or assumed symptoms of tumor is given at the risk of repeating what may be generally known.

Patients are classified as having verified tumors only when tissue has been submitted to a microscopic examination, whether obtained at operation or at autopsy, with the single exception that what were presumably gliomatous cysts were recorded in the past as verified, on the basis of the xanthochromic character of their fluid content.<sup>1</sup>

The group of unverified tumors comprises the cases in which the clinical examination leaves no doubt as to the presence of a tumor. In many instances, indeed, the growth may actually have been exposed at operation, but for one reason or another no fragment has been removed for histologic verification, this sometimes being inadvisable, as in the case of tuberculomas, or foolhardy, as in the case of certain highly vascular lesions. Naturally, a considerable number of patients with unverified tumors are not operated on at all. This is true of lesions that are unquestionably multiple and metastatic, as well as of

1. That this is not conclusive evidence of glioma has been pointed out by Cushing and Bailey in their monograph "Tumors Arising from the Blood Vessels of the Brain" (Baltimore, Charles C. Thomas, 1928), in which it has been made clear that xanthochromic fluid is no less characteristic of the cerebellar cysts with an angioblastic basis.

equally unmistakable tumors that are stationary, such as some of the subcortical gliomas undergoing calcification or certain of the inaccessible lesions of the craniopharyngeal pouch, which likewise may happen to be in a quiescent stage.

The suspected cases of tumor, though they form a most interesting group, are not recorded in these tables since many of them represent either patients who have been proved to have some disorder other than tumor or those in whom the diagnosis of tumor is open to reasonable doubt. Such conditions as aneurysm, abscess, chronic arachnoiditis, cerebral syphilis and vascular lesions and other states often spoken of as "pseudotumor" fall in this group. In a considerable percentage of these cases, an exploratory operation has been required before a diagnosis of tumor could definitely be excluded, and though these operations may be hazardous, as in the case of aneurysm, for example, the mortality resulting from the procedures in the cases of suspected tumor has been so insignificant that this group has been omitted in order to simplify the present report.

Under the caption "Operations" in the tables, all major procedures are included. These comprise: (1) explorations with partial or total extirpation of the tumor; (2) negative explorations with or without subsequent decompressive measures; (3) reelevations of bone flaps for postoperative complications, as well as (4) simple decompressions for the reduction of pressure symptoms as temporizing measures. The various punctures, lumbar, cisternal or ventricular, with or without the injection of air for diagnostic purposes, even though these measures have a certain attendant mortality, have not been included. As a matter of fact, ventriculography, when resorted to in this clinic for localization of tumors, is usually immediately followed by operation, so that the consequences of the preliminary procedure become fused with those of the subsequent one.

As will be seen, the number of operations exceeds the number of patients operated on, due in part to operations conducted in several stages, but more particularly to secondary procedures necessitated by a recurrence of symptoms. For example, a simple decompression after an interval may be followed by an osteoplastic exploration when localizing symptoms have become more definite; or an originally misdirected exploration may at a later time be succeeded by a secondary operation with exposure of the tumor and its partial or complete extirpation; or a patient may be operated on over and over again for a slowly growing recurrent glioma in a favorable situation.

Under the caption "Postoperative Deaths" are included all cases in which the patient died in the hospital, regardless of the time that had elapsed since the operation, and even though the fatality was definitely attributable to some cause other than the operation. However great

the temptation, an effort to divide the fatalities into those (1) obviously due to the operation, (2) remotely due to the operation and (3) independent of the operation would lead to confusion, to difference of opinion and to figures which for comparative purposes would be wholly unreliable.

The total number of operations, namely, 1,426, included in the first seven tables representing the six and one-half years since May 1, 1922, is more than half the entire number of operations in the whole series covering a period of almost thirty years, 2,716 operations having been performed since the first recorded case. This shows the notable increase in the number of patients with intracranial tumor who at present seek surgical relief. This unquestionably has been due to many factors, the most significant of them doubtless based on the fact that craniocerebral operations have become so commonplace that they are no longer regarded by either physician or patient as the desperate performances they were heretofore thought to be. As was once true of the major neuralgias, patients with this intolerable malady having been more often referred to operating clinics by former patients than by their physicians, so today the dread of intracranial procedures has so diminished that many patients under the suspicion of having tumor are referred directly to neurosurgical clinics on the recommendation of former victims of similar disorders.

The first six tables show that for the past six years there has been an average of 215 patients admitted or readmitted annually with tumor, verified or unverified, and that there has been about the same number of operations, 210 each year to be exact, or approximately eighteen operations a month, exclusive of those in the group in whom tumor was suspected. The tables also show a fairly steady annual increase<sup>2</sup> in the number of patients admitted, culminating in table 7 which gives the figures for the last eight months, that is, from May 1, 1928, to the date of the present writing. Indeed, it is often difficult to keep the number of admissions within reasonable limits so that they will not be out of proportion to other cases in what is actually a general surgical clinic. In spite of this, there may be occasionally as many as forty or more old or new cases of tumor under observation at a single time in the wards of the hospital.

The foregoing remarks are merely prefatory to the primary subject at hand, namely, a consideration of the mortality figures. These show, on the whole, a progressive tendency to improvement, notwithstanding the fact that, as years go on, more difficult and more radical operations

---

2. The considerable diminution in the number of operations shown in table 6 is accounted for by the absence of Dr. Cushing from the clinic for two months during that year.

# EISENHARDT—MORTALITY IN INTRACRANIAL TUMORS 1931

are being performed than were undertaken previously. The figures in the first table showing a mortality of 19.3 per cent for all the patients studied, and an operative mortality of 14.7 per cent, may be contrasted with those in table 7, showing a total mortality of 12.6 per cent and an operative mortality of 9.7 per cent. The temporary significant rise in the mortality figures shown in table 6 may be attributed to the fact that, during the early part of the twelve months represented, a considerable number of patients with tumors previously regarded as inoperable, owing to their inaccessibility or excessive vascularity, were

\* This includes a number of tumors of uncertain histogenesis together with a group of eleven malignant sarcomas, not yet reported on, which have had a high mortality.

readmitted and operated on by electrosurgical methods, the technic of which had not previously been fully developed.

Naturally, many factors greatly influence the mortality percentages, not the least of which is the surgeon's experience. In table 8 are shown, for purposes of comparison, the mortality figures for tumors in the Johns Hopkins Hospital series for approximately fifteen years to September, 1913, and the figures for the Peter Bent Brigham Hospital series for approximately the following fifteen years. In spite of the fact mentioned, that increasingly serious operations are being undertaken from year to year, step by step with the improvement in localization and increased knowledge of tumor histogenesis, the operative mortality has progressively diminished.

That the histologic nature of the tumor is another factor that has an important bearing is shown by table 9, in which are given the operative mortality figures for verified tumors only. In this table it will be seen that the highest mortality percentage is associated with the granulomatous tumors, this being due to the frequency with which tuberculous meningitis has followed, in the course of some weeks, the removal of a cerebellar tuberculoma. The lesions resulting in the next highest mortality are the metastatic tumors, a large number of the patients having subsequently died in the hospital at varying periods from an advance of their general disease. Next in order follow the gliomas, the acoustic tumors, the meningiomas, the cysts of the cranio-pharyngeal pouch and so on; finally, a marked drop in the mortality percentages occurs with the pituitary adenomas.

That there has been a vast improvement even in respect to the mortality for tumors of these various histologic types is shown by table 10,

TABLE 10.—*A Comparison of the Mortality Percentages for Verified Tumors in the Johns Hopkins Hospital and Brigham Hospital Series*

in which the operative mortality for the tumors of the major groups in the early Johns Hopkins and the later Brigham Hospital series are contrasted.

There are numerous other factors, apart from the surgeon's experience and the nature of the lesion with which he comes to deal, that definitely affect the operative mortality. Among these, perhaps the greatest emphasis may be laid on the importance of accurate pre-operative localizing diagnosis. There is a high mortality, for example, among cases of misdirected explorations. This is particularly evident, as Lehmann has pointed out in a study of the cases of subtentorial tumor observed in this clinic,<sup>3</sup> in those cases in which suboccipital explorations were performed for tumors which actually lay above the tentorium.

Unfortunately for purposes of comparison, the recent literature contains only a few reports in which the mortality figures of a series

3. Lehmann, W.: Zur Frage der Operationsmortalität bei subtentorialen Tumoren, Arch. f. klin. Chir. 143:552, 1926.

of operations for intracranial tumors have been given. Sachs<sup>4</sup> recorded 29 deaths (35.5 per cent) in a series of eighty-five cases, pointing out that the gliomas carry the highest percentage. Eiselsberg,<sup>5</sup> in giving the results of operations for tumors grouped according to their location, used as a basis for calculation of postoperative fatality a limit of four weeks; on this basis many of the cases recorded in the present series as fatalities would be excluded. He recorded 63 deaths (39 per cent) in 161 operations for cerebral tumors; 9 deaths (23.6 per cent) in 38 operations for pituitary tumors; 47 deaths (53.3 per cent) in 88 operations for cerebellar tumors, and 35 deaths (76 per cent) in 46 operations for cerebellopontile tumors. This gives an operative mortality of 46 per cent for the entire series.

Unquestionably the situation of the tumor has a great deal to do with the attendant risks, a suboccipital procedure in the long run being regarded by many as more dangerous than an operation for a lesion above the tentorium, yet Lehmann,<sup>3</sup> in a study of the fatalities following cerebellar explorations performed in the clinic of the Peter Bent Brigham Hospital, reported an operative mortality of 16.3 per cent for the 544 suboccipital operations in 433 cases; his figures, to be sure, included operations for suspected tumor as well as for actual tumor, whether verified or unverified.

For purposes of comparison with the figures herein given, the recent reports by Olivecrona and by Dowman and Smith are more suitable, since these authors have paid this clinic the compliment of employing its general method of classification. Olivecrona,<sup>6</sup> in his comprehensive monograph dealing with a series of eighty-five cases, in which 112 operations were performed, gave a total mortality of 40 per cent and an operative mortality of 30 per cent. All fatalities, from whatever cause, which occurred while the patients were still in the hospital were recorded as postoperative, regardless of the interval of time involved. Dowman and Smith<sup>7</sup> restricted their report to a review of 100 consecutive cases of tumors actually verified, in ninety-five of which the patients were operated on, 142 operations being performed. There were twenty-six deaths within the first twenty-four hours, and seventy-one deaths in the whole series, though it was not stated how long after operation the other fatalities occurred or whether the patients were still in the hospital.

5. Eiselsberg, A.: Probleme der Gehirn- und Rückenmarks-chirurgie, *Arch. f. klin. Chir.* **142**:203, 1926.

6. Olivecrona, H.: Die chirurgische Behandlung der Gehirntumoren, Berlin, Julius Springer, 1927.

7. Dowman, C., and Smith, W.: Intracranial Tumors: a Review of One Hundred Verified Cases, *Tr. South. Surg. & Gynec. A.* **40**:308, 1927.

In comparing the results of operations for intracranial tumors as reported from different hospitals, many elements, of course, must be taken into consideration. The general run of cases of tumor in some clinics may have a much more advanced syndrome than in the community where the present cases were observed, in which the local practitioners, at least, are apt to send patients in whom tumor is suspected to the hospital at an early date. There still are numerous patients, to be sure, who are sent from a distance, and, indeed, from the neighborhood, in the last stages of compression, with a choked disk that has gone on to blindness. The percentage of patients admitted who are near death, however, is unquestionably smaller than it was a decade or two ago. The fact that in the series of cases under discussion the mortality figures in the early years was far higher than at present has already been emphasized.

That the goal of an operative mortality of 10 per cent has been approximated during the last eight months of observation may be gathered from table 7. These comparatively low figures are due in large part to the extreme precautions taken against accident. Rarely is more than one major operation for tumor scheduled for one day. Most of the operations are carried through under local anesthesia, and all are started in this way. Patients who have been subjected to a craniotomy are not moved from the operating suite until the danger of the formation of a postoperative extradural clot has passed. After critical cerebellar operations, particularly if inhalation narcosis has been necessitated, the patients are usually left on the table for several hours until they have fully recovered, and they are often kept in the operating suite for a number of days. Those with deglutitory difficulties must often be fed through the nares for prolonged periods. For charity patients who are in a critical condition, from this or some other cause, special nurses are provided and paid for out of a fund donated for the purpose.

It is not my object in this paper to go into the causes of death. Olivecrona<sup>6</sup> has fully considered this phase of the subject, and our experience largely coincides with his. It may be said that infections are almost unknown, and that a death on the operating table is exceedingly rare. When it occurs, it is usually due to some condition that in retrospect might be seen to have been avoidable. Owing to the extreme care in the separate closure of the galea, there has been no example of postoperative fungus cerebri during the time that the present records have been kept. The more frequent causes of obvious postoperative fatalities have been from advancing pressure when no tumor has been found; or from a rapid recurrence of symptoms after cerebral edema;

from hyperthermia, particularly in young children with marked secondary hydrocephalus; and from an occasionally overlooked postoperative hematoma.

The mortality figures are chiefly affected by the fact that patients with recurring tumors, like those with some of the unfavorable gliomas, may be operated on over and over again, some of them for a period of many years with an almost inevitable ultimate postoperative fatality. The list of unverified tumors would be much larger than it is were it not that every effort is made to keep in touch with patients and their physicians so that the lesions may eventually be verified. One particular reason why tumors which have not been verified surgically show as high a mortality as they do is that the period of hospitalization of patients approaching death may be greatly prolonged in the expectation of determining the nature of the lesion. Records of the pathologic department show that the percentage of patients who are subjected to postmortem study is much higher on the neurosurgical service than in other departments of the hospital, which merely indicates the effort made in this direction.

Dr. Cushing said in his Cameron Lectures:<sup>8</sup>

The results of a series of operations for a given lesion in a given situation provide a score for the surgeon to play against; and an audience north of the Tweed need not be reminded of the importance of this as an incentive in improving one's game. Only by a carefully checked and posted score, such as is now available both for the acoustic tumours and for the pituitary adenomas, can a tentative "par" for the procedure in question be established. So we are constantly striving to better our record on the double basis of lower mortality percentages and of longer and more livable survival periods in the case of the more rapidly-growing tumours. A neurosurgeon's responsibilities would be insufferable if he did not feel that his knowledge of an intricate subject was constantly growing—that his game was improving.

# OBSERVATIONS ON THE LOCALIZATION OF INTRACRANIAL TUMORS

## THE DISCLOSURE OF LOCALIZING SIGNS FOLLOWING DECOMPRESSION OR VENTRICULOGRAPHY \*

HUGH CAIRNS

No one can have experience of intracranial surgery without perceiving how difficult it may be to localize an intracranial tumor, and how frequently operation is performed without the tumor being found. The object of this paper is to show that surgical intervention which falls short of removal of the tumor may so alter the signs and symptoms of the tumor as to enable a more accurate localization of its position to be made. Changes of a similar nature sometimes occur in cases of tumor of the spinal cord after lumbar puncture has been performed. These are easy to interpret and may therefore be conveniently considered before the more complicated changes that attend surgical intervention in cases of intracranial tumor.

### THE EFFECT OF LUMBAR PUNCTURE IN TUMORS OF THE SPINAL CORD

It is well known that withdrawal of cerebrospinal fluid by lumbar puncture may aggravate the signs and symptoms of a tumor of the spinal cord. The example may be quoted of an elderly lady who was carried into the Peter Bent Brigham Hospital suffering from paralysis of both legs. For the previous seven months she had complained of increasing weakness of the right leg, but she had been able to walk without assistance until one week before admission when, following a lumbar puncture, her legs became completely paralyzed. At operation, Dr. Cushing removed an intradural meningioma from alongside the midthoracic spinal cord and the patient made a complete recovery.

There is little doubt that in this case the withdrawal of cerebrospinal fluid by lumbar puncture was directly responsible for the great increase of physical signs, thus converting an uncertain clinical picture into one of obvious tumor of the spinal cord. Presumably the withdrawal of spinal fluid so altered the position of the tumor as to produce a greater degree of pressure on the spinal cord, or on its blood supply, with resulting loss of function.

It is thus seen that lumbar puncture, which might be termed a "minor injury" of the nervous system, is of value in diagnosis of

---

\* From the Surgical Service of the Peter Bent Brigham Hospital.

tumors of the spinal cord, not only because it frequently reveals characteristic changes in the spinal fluid, but also because it may so aggravate the preexisting signs and symptoms as to produce a clinical picture which is easily recognized as one pertaining to tumor. The changes which follow lumbar puncture may be much less prominent than those which occurred in the case of the old lady, and it is therefore important that after lumbar puncture in cases of suspected tumor of the spinal cord one should deliberately repeat the neurologic examination, in order to search for an extension of the physical signs. Increase in the signs may be taken as evidence of the presence of a tumor.

Observations of this nature have been made by numerous workers in the past, notably by Elsberg.<sup>1</sup> That analogous changes may be observed in cases of intracranial tumor does not appear to have been so generally recognized, yet it is clear from the examples presently to be described that such changes do occur and that they may become a vital factor in the successful conduct of any one case.

What forms of injury are likely to aggravate the signs and symptoms of an intracranial tumor? Withdrawal of cerebrospinal fluid by lumbar puncture will frequently do so, but to such extent that it may produce sudden death, and for this reason lumbar puncture is held to be dangerous in all cases of suspected intracranial tumor that show signs of hydrocephalus. The mechanism of herniation of the cerebellar tonsils and medulla oblongata through the foramen magnum, which is responsible for the fatalities after lumbar puncture, is well known, and therefore need not be elaborated here. The surgical procedure which more commonly than all others is seen to aggravate the signs of intracranial tumor is an osteoplastic exploration that fails to disclose the tumor. This is known in neurosurgical parlance as "the negative exploration."

#### THE NEGATIVE INTRACRANIAL EXPLORATION

When one considers that an expert neurologist after most thorough clinical examination may be unable to make an accurate diagnosis of the situation of an intracranial tumor, and that many parts of the brain are difficult of access, it is indeed not surprising that intracranial tumors are often difficult to find at operation, the more so as only a limited portion of the surface of the brain can be exposed at a single exploratory operation and the presence of a deep-seated tumor may be easily overlooked. The advent of ventriculography has provided an additional diagnostic weapon of great importance, yet this procedure is not so free from danger that it can ever supersede the exhaustive clinical investigations on which efforts to localize intracranial tumors have hitherto

1. Elsberg, C. A.: *Tumors of the Spinal Cord*, New York, Paul B. Hoeber, 1925, p. 255.

been based, and there are many cases of unlocalized tumor associated with secondary hydrocephalus in which its use is definitely contraindicated. In such cases the method of ventricular estimation may be used as an aid to diagnosis, but it not infrequently happens that a fairly confident opinion as to the situation of the tumor is formed on the history and physical signs alone, and the surgeon, without resorting to ventricular estimation, explores part of the brain by turning down an osteoplastic flap, and fails to find the tumor. He may then seek to reduce the raised intracranial pressure by leaving a decompression, and in this way many patients with intracranial tumors are temporarily relieved of their symptoms even though the tumor has not been removed. Experience teaches, however, that certain patients become definitely worse. This change for the worse that may follow a negative exploration and decompression has in the past played havoc with the peace of mind of pioneers in brain surgery, and a surgeon of experience has confessed to me that whenever he performed a craniotomy without discovering the tumor, he dreaded to approach the bedside on the following day for fear of finding that his patient had become afflicted with hemiplegia, aphasia or some other symptom that was not present before operation.

While in the past this aggravation of symptoms after a negative exploration and decompression was frequently due to gross injury of the brain at the time of operation, or to the formation of a postoperative clot, there is now, thanks largely to the work of Dr. Cushing, an operative technic so delicate that injury of the brain at operation can be avoided by all those who have the patience to master and employ the appropriate methods. If one may assume that the brain has been treated with proper gentleness at operation and that the operative field has been left dry, it is almost certain that any new signs and symptoms that make their appearance after operation must be due to alteration in the position or size of the tumor, occasioned by release of pressure in one part of the intracranial chamber. This obvious inference and all that it implies does not appear to have received in the past the attention that it deserves. Its importance was impressed on me by several cases that I saw during a year's experience as assistant resident surgeon to Professor Cushing, and particularly by the following case.

*CASE 1.—Glioma (astrocytoma) of the left temporal lobe. First operation: Negative exploration of the left occipital lobe. Alteration of the physical signs. Second operation: Subtotal removal of the tumor. Recovery.*<sup>2</sup>

2. I desire to thank Dr. Cushing for permission to report these cases. It is scarcely necessary for me to point out that, while I must shoulder the responsibility for any conclusions that have been reached, the central idea of this paper arose from observing him at work in case 1.

*Clinical History.*—Miss Z., aged 20, referred by Dr. Marvin L. Graves of Houston, Texas, was admitted to the hospital on Nov. 22, 1926

Her illness had begun nearly six years before with fleeting attacks of numbness of the right side of the body. These attacks were followed by "fainting spells" and, within a year, by generalized convulsions. After each convulsion she would have violent headache, mostly occipital, and vomiting for two to three days.

For eight months she had noticed that she could not see to the right, and had experienced a feeling of eye-strain and occasional diplopia. In addition, there had been some unsteadiness in walking and difficulty in swallowing; also some loss of memory.

*Examination.*—Examination showed bilateral papilledema with considerable secondary optic atrophy. There were signs suggesting cerebellar disturbance, namely, nystagmus, generalized hypotonia and ataxia, and staggering gait. But investigation of the visual fields showed complete right homonymous hemianopsia. There was also diminished sensation to pin-prick on the right half of the body. Spontaneous speech was normal, but there was slight difficulty in naming objects. The patient's speech, however, was examined by several observers and it was finally concluded that this questionable anomia was not significant.

*Diagnosis.*—The main signs were right homonymous hemianopsia, signs of cerebellar disorder and papilledema. The diagnosis thus lay between tumor of the left temporal and left occipital lobes. Looking back, it is difficult now to see how a mistake was made, but at the time the right-sided analgesia was disregarded and it was considered that absence of muscular weakness and of definite aphasia favored an occipital location. Occipital tumors and the cerebellar signs produced by them were being made the subject of special study at the time, and doubtless this weighed unduly in the decision to explore the occipital lobe.

*First Operation.*—Nov. 26, 1926: Dr. Cushing reflected an osteoplastic flap to expose the left occipital lobe. The brain protruded and everywhere showed flattening of the convolutions, but there was no sign of tumor. The left lateral ventricle was tapped and appeared to be displaced medially. In closing the wound it was necessary to sacrifice the bone of the flap.

*Postoperative Course.*—During convalescence the patient became obviously dysphasic and also showed marked weakness and spasticity of the right arm and leg, together with impairment of postural sensibility on the right side. These further signs considered in conjunction with the right homonymous hemianopsia left no doubt that the tumor was actually situated in the left temporal lobe.

*Second Operation.*—Jan. 6, 1927: Dr. Cushing turned down an osteoplastic flap over the middle portion of the left cerebral hemisphere, using the anterior limb of the former occipital exploration as the posterior limb of this new flap. In the cortex of the temporal lobe, and only 2 cm. in front of the area which had been explored at the previous operation, lay a large, soft avascular tumor. Tumor-tissue up to the size of a hen's egg was removed, mainly by suction. In closing the wound, it was again necessary to sacrifice the bone of the flap.

*Subsequent Course.*—After operation vision and speech improved, the headaches disappeared and the attacks of unconsciousness became less frequent. On discharge from the hospital, however, the patient still had some motor weakness and sensory loss over the right half of the body, also some difficulty in naming objects. The visual fields had not changed.

*Comment.*—The importance of this case to the present thesis lies in the great increase of physical signs which followed exploration and

decompression of the occipital region. A questionable difficulty in naming objects was converted into an obvious dysphasia. Paresis and disturbance of postural sensibility of the right side appeared as new signs. From knowledge of the localization of cerebral function, it is obvious that none of these signs could possibly have been due to local disturbance of the occipital lobe at or after operation, and the reasonable inference was that they were attributable to a tumor of the left temporal lobe which, as a result of the occipital decompression, had become altered in size or in its relation to the left cerebral hemisphere. The change is represented diagrammatically in the illustration. It is possible that withdrawal of fluid from the occipital horn of the left ventricle during the course of the first operation also played some part in the production of the fresh signs.

In *A* is shown the probable condition of affairs before operation. The presence of the tumor results in displacement of the falx cerebri to the opposite side. When the occipital decompression has been made (*B*) the occipital lobe bulges through the decompression. Owing to relief of pressure the falx tends to become straight. In addition the tumor is probably displaced backward. *C* shows the site of subsequent decompression.

What happened in this case may occur in other cases in which craniotomy has failed to disclose a tumor. After such an operation signs hitherto latent may declare themselves, and it is thus not infrequently possible to make a further and more accurate localization of the tumor and to repair the original mistake in diagnosis by a second operation. Recognition of this principle has not been sufficiently stressed in the past and doubtless in many cases its working has been overlooked because of a tendency to cease making neurologic examinations once operation has been performed. In many cases the changes are so slight as to be detected only by thorough examination. In other cases the

changes are more severe than in the foregoing case. The fatal hyperthermia which is so liable to follow in the wake of simple decompression-operations for tumors of the brain stem, such as pineal tumors,<sup>3</sup> and suprasellar cysts or adamantinomas,<sup>4</sup> is probably due to a shift in the position of the tumor in its relation to the vegetative centers of the hypothalamus. At present, however, too little is known of temperature control in man to render elaboration of this idea of any value.

It is clear that the possible effect of a shift of the tumor should always be considered when simple decompression operations are performed. When an osteoplastic exploration has been carried out and the tumor has not been found, there should not be any relaxation of clinical observation. Almost at once neurologic examination may reveal further signs which indicate unmistakably where the tumor lies, and the way will be open to retrieve the life and preserve the well-being of the patient by removal of the tumor at a second operation.

#### VENTRICULAR PUNCTURE AND VENTRICULOGRAPHY

The following case is one of several in which fresh signs and symptoms appeared after replacement of the fluid of one lateral ventricle by air.

*CASE 2.—Left frontal glioma. Ventriculography. Alteration of the physical signs. Operation: Left frontal osteoplastic exploration, subtotal removal of tumor. Recovery.*

*Clinical History.*—Mrs. M., aged 45, referred by Dr. L. G. Rice of Albuquerque, N. M., was admitted to the hospital on April 4, 1927. Her illness began fifteen months before admission with loss of energy and initiative. Nine months before admission, she began to suffer from headaches in the occiput and back of the neck. At this period her left leg began to drag while she walked, and at times it would give way and she would fall. After a vacation in August, 1926, she became much better and remained well, except for an occasional slight headache until February, 1927, when, six weeks before admission, the headaches and weakness of the left leg returned. The leg was so weak that she was unable to stand. Her left hand also became weak and in it she began to have attacks of numbness which lasted five minutes. Her speech became slow and she had difficulty in remembering the names of her friends. Her memory had been failing for about four months before admission. She was right-handed.

*Examination.*—The patient showed entire lack of anxiety about her condition, and was at times euphoric and subject to outbursts of excessive laughing. There was occasional incontinence of urine and feces. Bilateral papilledema was present. There was slight weakness, slight ataxia and dysmetria of the left arm and leg, and inability to stand. The left abdominal reflexes were absent. There was bilateral extensor plantar response.

3. Horrax, G., and Bailey, P.: Tumors of the Pineal Body, *Arch. Neurol. & Psychiat.* **13**:423 (April) 1925.

4. Critchley, M., and Ironside, R. N.: The Pituitary Adamantinomata, *Brain* **49**:437, 1926.

The case thus appeared to be one of tumor of the right frontal lobe, but some doubt was felt about this in view of the fact that the sense of smell was impaired on the left side. Further examination also showed occasional weakness of the right side of the face. It was therefore decided to do ventriculography.

*Ventriculography.*—The left lateral ventricle was tapped through the posterior parietal region, and 10 cc. of fluid was withdrawn and replaced by a similar amount of air.

Thirty minutes after the air was injected, while the ventriculograms were being developed, the right arm became extremely weak. There was also distinct weakness of the right side of the face, and speech became slurred.

The ventriculograms confirmed these recent clinical signs in showing a defect in the anterior horn of the left lateral ventricle.

*Operation and Subsequent Course.*—Accordingly, on the day after ventriculography, the left frontal lobe instead of the right frontal lobe was explored. A tumor was found at the anterior pole of the left frontal lobe. Over its surface was spread a delicate film of recent blood clot. The tumor, a glioma, was almost completely removed and the patient did well. Her mentality became normal and she was able to walk well before her discharge from the hospital about three weeks after operation.

*Comment.*—This case affords a good illustration of the way in which a tumor of one frontal lobe may simulate a tumor of the opposite lobe, but here it is only necessary to consider the alteration of physical signs that followed ventriculography and the manner in which it was produced. In this connection it is important to note that a thin film of blood clot was found on the surface of the tumor at operation. This clot was red, easily detached, and therefore evidently recent. There was, however, no reason to suppose that the clot was the result of hemorrhage during the course of the operation, for there was no injury of the dura during the preparation and reflection of the osteoplastic flap and the early stages of the operation were without incident. As soon as the flap was raised, the clot was visible through the dura mater as a circular bluish red area. In view of these observations it is probable that the clot was produced at the time of the ventriculography on the previous day. Withdrawal of fluid from the left lateral ventricle prior to the injection of air would tend to cause separation of the frontal lobe from the overlying dura mater and may thus have resulted in rupture of some delicate vessel passing between the dura mater and the surface of the tumor. It is always noticeable at operations that the anterior pole of the frontal lobe, more than any other part of the brain, tends to fall away from the overlying dura mater when the corresponding lateral ventricle is tapped.

As the air was injected into the left lateral ventricle by passage of a brain-needle through the left parietal region, it is necessary to enquire whether the weakness of the right arm and face and the slurring of speech which followed within thirty minutes of ventriculography may not have been due to disturbance at the site of tapping in the left

parietal lobe. There are no direct observations on this question, since neither the site of puncture nor the track of the brain-needle was inspected at the subsequent operation. In a personal experience of ventriculography performed through the parietal region, I have met with no other case that was followed by symptoms which could be referred to the site of brain puncture, but Dr. John Fulton, recently associated with Dr. Cushing, has related to me a case in which such symptoms occurred. In his case, however, the symptoms were not motor in character as in case 2, but consisted of numbness and tingling in the opposite hand which came on at the moment when the needle was being passed through the parietal lobe. In the case under discussion, it seems more reasonable to attribute the symptoms that appeared after ventriculography to disturbance of the tumor itself. And the blood clot which was found at operation on the surface of the tumor probably represents part at least of the disturbance.

The successful diagnosis and, depending so largely on the diagnosis, the successful outcome of this confusing case are to be attributed primarily to information furnished by the ventriculograms, yet interpretation of these was difficult and valuable evidence was obtained from neurologic examination of the patient after the injection of air. Ventriculography intensified the clinical picture so that what had hitherto been nebulous in the light of current neurologic knowledge now became clear.

#### THE MISUSE OF VENTRICULOGRAPHY

It is scarcely necessary to point out that provocation of an intracranial tumor by ventriculography is not a thing to be desired or deliberately sought after. The degree to which the signs and symptoms may be aggravated by injection of air cannot be accurately predicted or controlled, and a certain number of fatalities will inevitably occur if air is used in cases in which there is a severe rise of intracranial pressure, that is to say, in cases in which there is a high degree of papilledema, stupor or intense headaches and vomiting. There are, however, a number of other cases in which the rise of pressure is of but slight or moderate degree; in these cases ventriculography is clearly indicated, because no exact localization of the tumor can be made by clinical means, and the danger of failing vision precludes any delay. The fact that in such cases as these the symptoms may be aggravated or altered by injection of air is a clear indication that there should be as little delay as possible between ventriculography and removal of the tumor. The experience in case 2 shows that the disturbance occasioned by ventriculography may take effect quickly after the injection of air. In another communication,<sup>5</sup> I have reported a case of hydatid cyst of the

---

5. Cairns, H.: *A Study of Intracranial Surgery*, Medical Research Council, Special Report Series, no. 125, London, 1928, p. 43.

right occipital lobe in which, during the four days that followed ventriculography, the patient sank insidiously into a state of coma, from which he was rescued only by the most urgent measures. The literature now contains a number of records of cases of intracranial tumor in which the patient died a few days after ventriculography, though the relationship of injection of air to the aggravation of the patient's symptoms is not often commented on in the case reports.

Withdrawal of the air after the roentgenograms have been taken will mitigate to some extent the danger of ventriculography, but too much stress cannot be laid on the fact that ventriculography should be followed with all possible speed by removal of the tumor at operation. The use of ventriculography by any one who is not prepared to proceed, at once if necessary, with the surgical removal of the tumor is fraught with grave risks and can only bring discredit to a method which when properly used is a valuable adjunct to clinical investigation.

#### CONCLUSION

Evidence has thus been brought forward to show that the signs of intracranial tumors may alter after ventriculography and osteoplastic craniotomy and decompression. If these surgical procedures have been carried out with no error of technic the changes that occur in the clinical picture are to be attributed to change in position or size of the tumor itself. By recognition of this principle it is sometimes possible to make a successful diagnosis of the situation of a tumor that has already been sought for at operation without success. It is therefore advisable that such procedures as ventriculography and decompression should always be followed by careful neurologic examination.

Observations have been reported that indicate the manner in which ventriculography may endanger life, even in those cases in which its use is not contraindicated by the clinical condition of the patient. To prevent loss of life in these cases it is urged that ventriculography should be followed at the earliest possible moment by removal of the tumor.

# THE EXPERIMENTAL PRODUCTION OF MITRAL STENOSIS\*

JOHN H. POWERS

The experiments herein reported were undertaken with the aim of creating a chronic, sclerosing lesion of the mitral valve in dogs, as the primary step in an experimental study of the surgical treatment of mitral stenosis. Cutler<sup>1</sup> and his collaborators demonstrated that mitral insufficiency is well tolerated by previously normal dogs. Because of their inability to perform their operation on animals with stenosis, they were unable to ascertain whether or not the abrupt transformation of stenosis into stenosis with insufficiency could be similarly tolerated.

Consequently, this phase of the work, which might have been done in the laboratory, had it been possible to produce experimental stenosis in animals, was carried out on patients. A large segment was excised from the mitral valve of the fourth patient operated on by Cutler,<sup>1</sup> and also from the valve of a patient more recently operated on by Pribram<sup>2</sup> of Berlin. Both patients died of pulmonary congestion and cardiac failure. The operative procedure was successful in each case. A large segment of valve was removed and a pronounced regurgitation was established; yet the patients died. Obviously, before real progress can be made, it will be necessary to establish by experimental methods whether or not partial valvectomy is a justifiable procedure in cases of mitral stenosis.

## HISTORY

Early in the year 1902 appeared the suggestion by Sir Lauder Brunton<sup>3</sup> that, "the good results which have been obtained by surgical treatment of wounds in the heart emboldens one to hope that, before very long, similar good results may be obtained in cases of mitral stenosis." A storm of comments, criticisms and protests followed this proposal. The technical difficulties of the procedure were great, but the whole field of surgery at that time was making rapid progress. A mechanical respiratory apparatus had been developed for administering an anesthetic under positive pressure so that the chest might be opened without collapse of the lungs, and the thorax soon became a favorite field for investigation.

3. Brunton, L.: Preliminary Note on the Possibility of Treating Mitral Stenosis by Surgical Methods, *Lancet* **1**:352, 1902.

In 1907 appeared the first paper on the creation of a temporary mitral stenosis, by Cushing and Branch.<sup>4</sup> This was accomplished by placing a purse-string suture around the base of the mitral valve which, when tightened, approximated the papillary muscles and chordae tendinae and prevented complete relaxation of the mitral leaflets during diastole.

Two years later, Bernheim<sup>5</sup> attempted similar experiments, using a fine silver wire. After producing a partial stenosis he planned to cut the wire and allow the circulation to return to normal, thus simulating what he hoped might be obtained by notching a stenosed human valve. Only one of his experiments was successful.

A few years later Carrell<sup>6</sup> and Tuffier attempted to create mitral stenosis by suturing together the leaflets of the valve under direct vision. Thermocautery of the aortic valve was also performed. Both operations were carried out with the circulation closed, a method which entails temporary obstruction of the cerebral blood supply. Many investigators have demonstrated that the cerebral anemia which accompanies such a procedure produces undesirable sequelae.

Cutler, Levine and Beck<sup>7</sup> attempted to narrow the mitral orifice by plication and radium. A wedge-shaped portion of myocardium with the apex pointing toward the endocardium was removed and the gap reapproximated. Neither this method nor the use of a ligature placed about the base of the mitral ring proved successful in producing a permanent stenosis. They then resorted to the proposal of Coryllos, Edwards and Bagg,<sup>7</sup> hoping to produce a contracting scar by the use of radium. From four to twelve radium emanation seeds (1 to 8 millicuries) were inserted around the base of the mitral ring by needles and left in place. Some animals died from coronary hemorrhage due to erosion into the vessels. Others showed dense, firm scars at the site where the seeds were deposited and a tendency of the valvular segments to retract. The chief difficulty in the procedure lay in their inability to slide the radium out into the leaflets of the valve. This is not surprising when one considers the fact that the leaflets are in constant motion and that attempts at localization were, of necessity, guided by the sense of touch alone.

## EXPERIMENTAL METHODS

The contracted, fibrosed, and often calcareous orifice of mitral stenosis is the result of long-standing irritation both in the leaflets of the valve and in the ring at their base. The causal factor of rheumatic endocarditis is obscure. It is well known, however, that vegetative lesions may be engrafted only on primarily injured endocardium. In an effort to produce chronic irritation of the mitral valve in dogs, two distinct procedures have been carried out: (1) traumatization of the valve by electrosurgical methods, and (2) intravenous inoculation with cultures of streptococcus.

*Electrocoagulation of the Mitral Valve.*—A portable diathermy apparatus producing a bipolar current of high frequency was used. The operative technic involving exposure of the heart and the control of hemorrhage was similar to that employed by Cutler, Levine and Beck.

One half hour after the administration of morphine hypodermically, the dog is anesthetized with ether and both sides of the thorax are shaved and cleansed with soap and water. When the animal is fully relaxed, a properly fitting rubber tube is introduced through the larynx into the trachea and attached to a Wolf bottle containing ether, which is, in turn, attached to the Erlanger mechanical respiratory apparatus. The dog is turned on its right side with a pad beneath the midthorax. The indifferent electrode is placed in direct contact with the skin. Both fore and hind legs are extended and held in position with web straps. The operative field is prepared with iodine and alcohol; the dog and the operating table are draped with sterile sheets. Incision is made over the left fifth or sixth rib from the angle almost to the sternal junction, and carried down through the fascia and muscles to the periosteum. The exposed rib and a portion of the costal cartilage are resected subperiosteally and the pleura is opened. When the lungs are packed off with two warm, moist, saline pads of cotton, a satisfactory exposure of the heart is obtained. The sterile portion of the electrode is then attached to the remainder of the apparatus and tested.

The pericardium is incised just medial to and parallel with the left phrenic nerve, the heart is delivered from the pericardial cavity by a spoon-shaped spatula, and a suture is placed in the apex to facilitate subsequent manipulation. A spot for the incision is chosen on the anterior surface of the left ventricle, free from coronary vessels and about midway between the apex and base. Control sutures are placed on each side of this area; the ends are crossed and held by the assistant. The myocardium is incised and the insulated electrode introduced into the cavity of the ventricle. By invaginating the auricular wall with the left forefinger, the operator is able to localize the tip of the instrument in the mitral orifice. When the tip is accurately placed on the under surface of the leaflet of the valve, at its junction with the mitral ring (fig. 1), the current is applied. When the valve has been sufficiently traumatized, the instrument is withdrawn and the wound in the heart is closed with two or three silk sutures. The apex and control sutures are removed, the heart is replaced in the pericardial cavity, and the pericardium is closed with a continuous stitch of fine silk. The cotton pads are removed, the lungs are inflated, and the pleura and chest wall are closed in layers. If carefully performed, the operation should be quite bloodless throughout.

*Intravenous Inoculation with Streptococci.*—In order to increase the reaction in the traumatized valve and create an additional cause for cicatrization, acute vegetative endocarditis was superimposed.

Two strains of streptococci were used, a *Streptococcus viridans* isolated by Dr. Zinsser from the myocardium of a child who died of

Fig. 1.—Operative sketch. The roof of the left auricle has been invaginated with the index finger of the left hand and the tip of the electrode is being approximated to the inferior surface of the lateral leaflet of the mitral valve. Hemorrhage is controlled by traction on the crossed sutures at each side of the myocardial incision. *A* indicates the tip of the electrode; *B*, the mitral valve; *C*, the pericardium; *D*, the left lung (packed off); *E*, the left auricular appendage; *F*, the pulmonic artery; *G*, the aorta; *H*, the parietal pleura; *I*, the interventricular septum, and *J*, the right ventricle.

rheumatic fever, and the *Streptococcus cardio-arthritis* of Small.<sup>8</sup> On the second postoperative day, each dog to be inoculated was given, intravenously, from 30 to 50 cc. of a twenty-four hour broth culture. On the fourth day, a second injection of from 70 to 100 cc. was given. Two days later, a blood culture was taken. Several normal animals were inoculated in a similar manner, for the purpose of controls.

#### COMMENT

During each operation, an effort was made to create as much valvular damage as could be tolerated by the animal. Mitral regurgitation was the immediate result of the procedure. The leaflets of the valve were charred and puckered (fig. 2) and a systolic murmur was audible on

Fig 2—The immediate effect of electrical coagulation of the mitral valve and ring. There is charring at the base of the valve, the leaflets are retracted and a moderate insufficiency is apparent.

auscultation. If the regurgitation was too severe, the heart gradually dilated, occasionally to almost twice its original size; its beats became less and less forceful, and the dog soon died of cardiac failure. Ventricular fibrillation and death were observed in a few cases in which the base of the aortic leaflet had been destroyed. This may have been caused by damage to the auriculoventricular node.

In order to determine the effect of coagulation alone, eight dogs were not inoculated after operation. When their hearts were subsequently examined, small fibrous scars were found in the mitral ring.

<sup>8</sup> Small, J C : The Bacterium Causing Rheumatic Fever and a Preliminary Account of the Therapeutic Action of Its Specific Antiserum, Am. J. M. Sc. **173**: 101, 1927.

The leaflets of the valve were not thickened and the orifice was not contracted.

All the other animals had intravenous injections of cultures of streptococcus in the manner previously outlined. No elevation in temperature occurred and no evidence of a generalized systemic reaction was apparent. Within twelve hours after the first inoculation with the *viridans* strain, tiny discrete vegetations were discernible on the free edges of the traumatized valve. As the infection progressed, the vegetations increased in size, and at the end of a week, appeared as rounded, discrete or confluent, pinkish, warty tumors, from 1 to 3 mm. in diameter (fig. 3). A culture which was taken two days after the second inoculation showed from 2 to 100 organisms in 0.5 cc. of blood. As

Fig. 3.—Acute vegetative endocarditis of the mitral valve. The animal was sacrificed one week after the second inoculation with *Streptococcus viridans*. The untraumatized tricuspid valve was normal in spite of the fact that streptococci were constantly circulating in the blood stream.

far as could be determined, the infection pursued one of two courses from this point onward:

1. If the dog developed resistance, the bacteremia remained essentially the same or increased, the vegetations grew into huge, fungating lesions, and the course of the disease followed that of subacute bacterial endocarditis in human beings. The systolic murmur became more pronounced and no diastolic murmur appeared. Occasionally ball thrombi formed on the valve. Death eventually occurred from septic infarction or embolism of the great vessels.

2. If the acute vegetative process healed, the leaflets became thickened and fibrosed. Dense, cartilaginous scars formed at the base of the leaflets where the mitral ring had been traumatized. These cicatrices

frequently extended well into the substance of the myocardium and a real stenosis of the orifice was apparent.

Reoperation followed by reinoculation was frequently necessary before sufficient reaction occurred to produce a chronic, sclerosing, stenotic lesion.

The dogs which were not operated on but were injected had positive blood cultures for only a few days after inoculation. No evidence of endocarditis was apparent when the hearts were subsequently examined.

Postmortem examination of the hearts of all the dogs subjected to operation showed no lesions on any of the valves except the one which was traumatized by the operative procedure.

Routine electrocardiograms and roentgenograms of the heart at 1 meter were taken before operation and at intervals during the post-operative course. A noticeable increase in the transverse diameter of the heart occurred in many cases, and the dogs with marked stenosis

Fig. 4.—Roentgenograms of the heart demonstrating increase in the transverse cardiac diameter and dilatation of the left auricle. The animal was operated on immediately after the first plate was taken on January 6, and inoculated with *Streptococcus viridans*. It was reoperated on and reinoculated after the second plate was taken on February 21. The animal was sacrificed after the third roentgenologic examination on September 17. Thickening, fibrosis and stenosis of the mitral valve were found.

showed a slight prominence of the left auricular region (fig. 4). Electrocardiographic tracings showed no definite variations from the normal.

#### RESULTS OF EXPERIMENTS

Fifty-seven operations were performed. Seven dogs died on the table from too severe a regurgitation, and six others from ventricular fibrillation. The immediate operative mortality was, therefore, 22.8 per cent. Two dogs died from a ruptured heart, one on the fifth day, and one on the seventh day, after a second operation. Because of improper sterilization of the electrode during the early experiments three dogs died from purulent pericarditis and empyema of the pleura. The cause of death in one case was undetermined. These fatalities, added

to the immediate operative deaths, made the total operative mortality 33.3 per cent.

Eight dogs were not inoculated. All had systolic murmurs but only one developed a diastolic rumble. This animal was sacrificed at the end of nine months and two small, firm scars were found at the base of the mitral ring. These may have produced some restriction of the orifice during diastole. One animal died unaccountably eight months after operation and another was sacrificed at the end of nine months. Postmortem examination of the hearts showed insufficiency of the

Fig. 5.—A ball thrombus attached by a slender pedicle to the superior surface of the mitral valve. Death occurred three weeks after operation and inoculation with *Streptococcus cardio-arthritis*. An embolus, which had presumably been detached from the same pedicle, was found at the bifurcation of the abdominal aorta.

mitral valve, slight scarring around the ring, but no stenosis. One dog died of distemper, and four were reoperated on and received injections.

Five animals were inoculated with *Streptococcus cardio-arthritis* (strain R<sub>1</sub>) after operation. All developed acute vegetative endocarditis and systolic murmurs. Two died of embolism at the bifurcation of the abdominal aorta and gangrene of the extremities. Examination of the hearts revealed a large, cauliflower-like vegetation on the mitral valve of one, and a ball thrombus attached by a slender pedicle to the valve of the other (fig. 5). One animal died of distemper, five weeks

after inoculation. Postmortem examination of the heart revealed sclerosis and the formation of fibrocartilage at the base of the mitral ring but no restriction of the orifice and no thickening or fibrosis of the leaflets.

Ten dogs were operated on and inoculated with *Streptococcus viridans*. One died within a few hours, from what appeared to be an anaphylactic reaction. One animal developed no cardiac murmurs and had a positive blood culture for only a few days. When the heart was subsequently examined, the mitral valve appeared normal, but several scars were apparent on the roof of the left auricle. The tip of the electrode had evidently been passed through the mitral orifice and placed in contact with the endocardium of the auricle. One dog failed to develop acute endocarditis and was sacrificed at the end of one month. The operative procedure had again been unsuccessful, for the mitral valve appeared normal.

All the other animals developed acute vegetative endocarditis, a positive blood culture, and a systolic murmur. Two were sacrificed, at the end of one and two weeks, respectively, in order to study the pathology of acute endocarditis. One developed no resistance to the infection and died on the sixtieth day from septic infarction of the kidneys and embolism of the femoral artery. Examination of the heart revealed a huge fungating vegetation on the mitral valve (fig. 6). Two animals developed hyperactive hearts, loud snapping first sounds, and blowing systolic murmurs, but no adventitious diastolic sounds were ever audible. Both were sacrificed at the end of four months. Postmortem examination of the hearts revealed moderate thickening, scarring, and some retraction of the mitral leaflets sufficient to produce incompetency of the valve, but no stenosis of the orifice. One animal developed an accentuated first cardiac sound, a moderate systolic murmur and a short, early diastolic rumble; it died at the end of four months. Autopsy failed to reveal the cause of death. There was marked thickening and fibrosis of one mitral leaflet, a deep scar in the mitral ring and moderate stenosis of the orifice.

One dog was reinoculated several times. Each inoculation was followed by a positive blood culture which was considered to be indicative of an acute process superimposed on the old healed lesion. The animal was sacrificed nine months after operation. One leaflet of the mitral valve was definitely thickened and the orifice was moderately contracted (dog 17).

One animal, operated on twice but inoculated with *Streptococcus viridans* only after the second operation, died on the forty-third day, from chronic passive congestion and cardiac failure due to severe mitral stenosis. The clinical signs of stenosis, which were present before

death, included a moderately loud systolic blow, no second sound, and a short, early diastolic murmur (dog 19).

Seven dogs, operated on and inoculated with *Streptococcus viridans*, developed acute vegetative endocarditis. During the next three months, the bacteremia disappeared and the acute process subsided. All the dogs were reoperated on; at the second operation, a stenosis of the mitral orifice and multiple scars around the ring were palpable in every case. Each animal was reinoculated in the usual manner and again developed acute endocarditis. The lesions healed much more rapidly the second time, due undoubtedly to the resistance developed in over-

Fig. 6.—Fungating vegetative endocarditis of the mitral valve. The dog's clinical course was typical of acute bacterial endocarditis. Death was due to septic infarction of the kidneys and embolism of the femoral artery.

coming the initial infection. One animal was sacrificed seven months after the second operation. A well marked stenosis of the mitral valve was present (fig. 7). The leaflets were much thicker than normal and were tough, fibrotic and sclerosed (fig. 8). Histologic examination showed the formation of fibrocartilage around the base of the ring, fibroblastic invasion and the formation of new blood vessels in the leaflets of the valve. The histologic studies of the tissues of acute endocarditis, organizing valvular thrombi, and mitral stenosis will be reserved for a subsequent paper. The remaining six dogs are still alive and five of them present clinical evidence of mitral stenosis.

Fig 7.—Stenosis of the mitral valve. The animal was operated on twice, inoculated after each operative procedure, and sacrificed at the end of seven months. The leaflets were much thicker than normal, fibrotic and sclerosed. The cordae tendineae were thickened and contracted.

Fig. 8—Vertical sections through the valve and mitral ring of the heart shown in figure 7 and through a corresponding position in a normal heart for comparison (actual size). The leaflet in the section at the left is densely scarred, markedly thickened, and almost calcareous in consistency. At the base of the ring is a dense, firm cicatrix extending well into the myocardium and composed largely of cartilage. The section at the right is from the heart of a normal dog; the leaflet is thin, soft and pliable.

It seems unnecessary to include protocols of all the experiments, and only the following two, therefore, are presented.

#### REPORT OF TWO EXPERIMENTS

Dog 17.—A mongrel bull terrier, female, weighing 15.1 Kg.

Dec. 13, 1927: A roentgenogram was taken of the heart at a distance of 1 meter (fig. 9) and an electrocardiographic tracing was made.

*Electrocoagulation of Mitral Valve.*—The anesthetic was ether, administered intratracheally by the Erlanger apparatus. The dog was placed on its right side with a pad and the indifferent electrode beneath the thorax. After the skin was shaved and cleansed with soap, water, ether, iodine and alcohol, the chest was opened by incision over the fifth rib and subperiosteal resection of the anterior portion of the rib and its costal cartilage. The pleura was incised and the lungs were packed off with pads of cotton moistened in warm saline solution. The pericardium was opened by an incision anterior to and parallel with the left phrenic nerve. The heart was delivered from the pericardial cavity by a spatula and a suture was placed in the apex to facilitate manipulation. Two control sutures were placed in the anterior surface of the left ventricle about midway between the apex and base. The myocardium was incised between the control sutures, and the tip of the sterile portion of the electrode was introduced into the cavity of the left ventricle. By invaginating the roof of the left auricle it was possible to palpate the tip of the instrument in the mitral orifice (fig. 1). The valve and ring were coagulated on their anterior, lateral, and posterior aspects. Slight dilatation of the heart occurred but the cardiac mechanism was not disturbed. The electrode was removed and the myocardial wound was closed with three sutures of C silk. There was no bleeding. The pericardium was closed with a continuous suture of A silk, the lungs were inflated and the pleura and posterior periosteum were closed with a continuous suture of C silk. The fascia and muscles were closed with C silk, the subcutaneous tissues with A silk, and the skin with A silk. The dog was in good condition at the end of the operation. No murmurs were audible.

December 15: The dog was up and walking about. No murmurs were audible.

December 17: The dog was in good condition. No murmurs could be heard.

December 21: A well marked systolic murmur was present. The wound was clean and healing by first intention. The sutures were removed.

Jan. 9, 1928: The murmur was unchanged.

February 7: The murmur was faint. The temperature was 102 F. The animal was inoculated intravenously with 30 cc. of a twenty-four hour broth culture of *Streptococcus viridans*.

February 8: The temperature was 101.6 F.

February 9: The temperature was 101.6 F. One hundred cubic centimeters of a twenty-four hour broth culture of *Streptococcus viridans* was injected intravenously. The murmur was slightly louder than before inoculation.

February 10: The temperature was 101 F.

February 11: The temperature was 101 F. One hundred cubic centimeters of a forty-eight hour broth culture of *Streptococcus viridans* was injected.

February 18: The blood culture was positive.

March 7: With the dog lying on the left side, a harsh systolic and soft diastolic murmur were audible. The first cardiac sound was loud and snapping; the second sound was less distinct. A roentgenogram of the heart was taken at a distance of 1 meter.

March 9: An electrocardiographic tracing was made. Dr. S. A. Levine of the Peter Bent Brigham Hospital listened to the dog's heart and stated: "The first sound is slightly snapping in quality and the second sound is good. There is a systolic blow after the first sound and a short rebound in very early diastolic. Presystole is clear."

May 7: The diastolic murmur was not audible; the systolic murmur was the same. A blood culture and a roentgenogram were taken (fig. 9).

May 10: The blood culture was positive, showing one colony.

May 21: Seventy cubic centimeters of *Streptococcus viridans* was injected intravenously.

May 28: The blood culture was positive, showing four colonies.

June 7: There was a heaving cardiac impulse and the first sound was snapping in quality.

July 13: Both systolic and diastolic murmurs were present. A blood culture was taken.

July 16: The blood culture was negative.

July 19: One hundred cubic centimeters of a fresh twenty-four hour culture of *Streptococcus viridans* was injected intravenously.

Fig. 9.—Roentgenograms of the heart of dog 17, the first one taken on Dec. 13, 1927, before operation, the second, on May 17, 1928, and the third on September 12. There is a definite change in the shape of the heart; the last plate shows a decided prominence in the region of the left auricle and slight increase in the transverse cardiac diameter.

July 27: The blood culture was positive, showing four colonies.

August 6: There was a definite systolic thrill. The second sound was followed by a short early diastolic whiff (Dr. Levine). The blood culture taken the previous day was negative.

August 31: Eighty cubic centimeters of a broth culture of streptococcus was injected intravenously.

September 4: Eighty cubic centimeters of the same culture was injected.

September 6: A blood culture was taken.

September 10: The blood culture was positive, showing five colonics.

September 12: A systolic thrill was palpable and an early diastolic murmur was heard, extending into middiastole. An electrocardiogram and a roentgenogram were taken (fig. 9) and the dog was sacrificed.

*Autopsy.*—The wound in the thoracic wall was firmly healed. There were a few filmy adhesions between the left lung and the pericardium at the site of the pericardial incision. There were dense adhesions between the pericardium and myocardium in the vicinity of the myocardial wound. The heart was removed and opened. There were two dense firm scars in the mitral ring. One leaflet of the

valve was thickened and sclerosed. The orifice was moderately restricted. Two tiny fresh vegetations were found on the leaflets.

Dog 19.—A brown and white bull terrier, male, weighing 11.8 Kg.

Dec. 19, 1927: An electrocardiographic tracing was made.

December 20: A roentgenogram was taken.

*Electrocoagulation of the Mitral Valve.*—The anesthetic was ether, administered by the Erlanger respiratory apparatus. The operative procedure was that described in the previous protocol. No murmurs were audible at the end.

December 21: The dog was in good condition. Auscultation of the heart revealed what seemed to be a soft systolic murmur, but extraneous pericardial sounds made it impossible to distinguish the murmur with certainty.

December 30: The wound was well healed by first intention. The cutaneous stitches were removed.

Jan. 9, 1928: A questionable systolic murmur was present.

February 3: No definite murmur could be heard. The dog was reoperated on.

Fig. 10.—Experimental stenosis of the mitral valve. The leaflets are thickened and sclerosed, the edges are searched together and the orifice is markedly contracted. The dog died of cardiac failure and chronic passive congestion of the lungs and liver.

*Secondary Coagulation of Mitral Valve.*—The anesthetic was ether, administered by the Erlanger apparatus. The chest was opened through an incision parallel with, and 1 cm. cephalad to, the scar of the previous operation. There were no adhesions between the lungs and the pleura or pericardium. The pericardium was adherent to the epicardium at the site of the old myocardial incision. Because of these adhesions, the heart was not delivered from the pericardial cavity and no apex suture was necessary. The control sutures were placed in the anterior surface of the left ventricle near the base. The myocardium was incised, the electrode was introduced, and the mitral valve was coagulated anteriorly, posteriorly, and laterally. The heart stopped beating. The instrument was immediately withdrawn, the myocardial wound was closed with one suture of C silk, and the heart was resuscitated by manual massage. The pericardium and thoracic wall were closed as usual. The dog was in fair condition at the end of the procedure. A soft systolic murmur was audible.

February 7: The dog made a good recovery. A definite systolic murmur was present. The temperature was 101.4 F. Thirty cubic centimeters of a twenty-four hour broth culture of *Streptococcus viridans* was injected intravenously.

February 9: The temperature was 101 F.

February 11: The temperature was 101.6 F.

February 13: The temperature was 101.6 F. The murmur was scarcely audible.

February 18: The dog was inoculated with 70 cc. of a twenty-four hour broth culture of *Streptococcus viridans*.

February 20: A blood culture was taken. The murmur was loud and blowing in character.

February 24: The blood culture was positive, showing several colonies.

March 9: An electrocardiogram and roentgenogram were taken. Dr. Levine listened to the dog's heart and stated, "there is a moderately loud systolic murmur, no second sound, and a short early diastolic murmur." A blood culture was taken.

March 11: The blood culture was positive, showing one colony.

March 14: The dog refused food, was very inactive, and made no effort to stand. There was no edema of the extremities.

March 16: The dog continued to refuse food and was growing more lethargic.

March 17: The dog was found dead in the cage.

*Autopsy.*—The wound was firmly healed. There were no adhesions between the lungs and pleura, only one between the lungs and pericardium, but many filmy adhesions were found between the pericardium and epicardium. The lungs were moderately congested. The liver was enlarged, soft and congested. There was no fluid in the peritoneal cavity. The heart was removed and the roof of the left auricle was opened. The mitral valve was tremendously thickened, fibrotic and sclerosed. The leaflets were seared together, and the orifice was markedly contracted (fig. 10).

#### CONCLUSION

Vegetative endocarditis of the mitral valve may be produced in dogs by electrocoagulation of the valve, followed by the injection of cultures of streptococcus into the blood stream. If the animal develops no resistance to the infection, the disease pursues an acute course similar to that of bacterial endocarditis in human beings. If the acute process subsides, the vegetative thrombi become organized, fibrosis occurs and the valve becomes thickened and sclerosed. Fibrocartilage is deposited around the base of the ring. The orifice is constricted and in favorable cases, the end-result is experimental mitral stenosis comparable in its clinical, gross pathologic, and mechanical aspects to the stenosis seen in chronic cardiac valvular disease in man.

# THE EXPERIMENTAL PRODUCTION OF PULMONARY ABSCESS

ETIOLOGIC FACTORS \*

JOHN E. SCARFF

The relationship between chronic infection in the upper respiratory tract and the development of pulmonary abscess is of great experimental interest and equal clinical importance. The recent work from Cutler's laboratory,<sup>1</sup> demonstrating that abscesses of the lung may be caused in dogs by embolic processes, does not prove that all abscesses arise in this way. The fact that many of these lesions—such, for instance, as those following epileptiform seizures—cannot be explained on an embolic basis suggests a search for other sources of the infection and directs attention to chronic suppurations in the upper air passages.

In 1923, Kline<sup>2</sup> injected material, removed from the mouth and teeth of a man who had died of pulmonary gangrene, into the trachea of rabbits, and obtained small localized areas of pulmonary "gangrene." In 1927, Smith<sup>3</sup> reported the development of pulmonary abscesses in mice and rabbits after the introduction into the trachea of scrapings from pyorrheal cavities in man, but was unable to reproduce these lesions in dogs. In 1927, also, Crowe and Scarff,<sup>4</sup> in a brief preliminary communication, reported abscesses of the lungs in dogs, made by introducing into the bronchi of these animals cotton pledgets inoculated with pus obtained from chronically suppurating frontal sinuses in dogs, which they had established experimentally, and infected material scraped from pyorrheal cavities in man. In 1928, Allen<sup>5</sup> reported

evidence of beginning cavity formation in the lungs of dogs following intratracheal insufflation of pus from the abscessed lungs of human beings and ligation of the bronchus leading to the inoculated lung.

The present paper describes the experiments which led to the development of pulmonary abscesses in dogs mentioned in the preliminary statement referred to previously, and, in addition, describes a number of experiments carried out more recently for the purpose of determining, if possible, fundamental pathologic principles underlying the formation of these abscesses.

#### EARLY UNSUCCESSFUL ATTEMPTS TO PRODUCE ABSCESS OF THE LUNG

Over fifty experiments, all under anesthesia, were carried out by the following methods without obtaining one abscess.

##### BRONCHOSCOPIC METHODS

*Simple Destruction of Pulmonary Tissue (Eight Experiments).—*Destruction was effected by use of electrical cautery and by acids applied through a bronchoscope. Prompt healing resulted in all cases. No abscesses developed.

*Introduction of an Infected Foreign Body into a Bronchus (Five Experiments).—*Cotton pledgets inoculated with various organisms were passed into secondary bronchi through a bronchoscope after slight abrasion of the mucous membranes. *Staphylococcus aureus*, *Staphylococcus albus*, mixed cultures from a dog's mouth, organisms recovered from an abscess on the body of a dog and cultures from the nostrils of a dog suffering with distemper were all used as inoculating agents. No abscesses and no distemper resulted.

*Introduction of a Nut into a Bronchus (Four Experiments).—*Freshly roasted whole peanuts were used. One dog dislodged the nut during the first six hours and recovered. The other three dogs immediately developed overwhelming generalized bronchitis and bronchopneumonia and died. These results were strikingly in agreement with statements of Jackson<sup>6</sup> that nuts produce unusually acute reactions when aspirated into the lungs of children.

##### TRANSPLEURAL EXPERIMENTS

All bacterial inoculations mentioned in the transpleural experiments were made with 1 cc. of heavy saline emulsions of eighteen hour growths of bacteria introduced into the lung through a long needle under fluoroscopic guidance.

6. Jackson, Chevalier: Observations on the Pathology of Foreign Bodies in the Air and Food Passages. Surg. Gynec. Obsl. 28:201, 1919.

*Simple Destruction of Pulmonary Tissue (One Experiment).—*One cubic centimeter of boiling water was injected into a lobe. There were no significant sequelae.

*Simple Infection Introduced into Pulmonary Tissues (Four Experiments).—*The injection of 1 cc. of warm agar was followed, after a suitable interval, by the injection of *Pneumococcus* type I (three animals) and *Streptococcus hemolyticus* (one animal). There were no significant postoperative sequelae.

*Tissue Destruction Plus Infection (Thirteen Experiments).—*One cubic centimeter of boiling water was first injected into a lobe of the lung, and the needle was left in place. After approximately twenty minutes, organisms were introduced through the same needle into the devitalized tissues. The following organisms were used: *Staphylococcus aureus* (one animal), *Staphylococcus albus* (one animal), cultures from a dog's mouth (one animal), cultures from the nostrils of dogs with distemper (two animals), thick suspensions of fecal material of a dog (one animal), 2 cc. of dog's blood mixed with 2 cc. of heavy emulsions of *Staphylococcus aureus* (one animal), pathogenic *Sporothrix* from a man (four animals) and sputum from a pulmonary abscess in a human being (two animals). There were no significant postoperative sequelae. All lesions healed quickly leaving small white scars.

*Tissue-Destruction Plus Foreign Body Plus Infection (Five Experiments).—*Through intercostal incisions, small metal foreign bodies were placed in the center of the lower lobes in five dogs; the lobes were then stitched to the wall of the chest. Two or three weeks later, with a long needle under fluoroscopic guidance, the following organisms were transpleurally introduced on the foreign bodies: *Staphylococcus aureus* (one animal), *Streptococcus hemolyticus* (one animal), culture of organisms from the mouth of a dog (one animal), and suspension of fecal material from a dog (one animal). The fifth dog developed distemper before experimental inoculation could be made into the lung. From this, however, he recovered completely. When the animals were killed some eight weeks later, autopsy in all cases showed pieces of metal firmly encapsulated in scar tissue without any evidence of active inflammation or the formation of cavities.

Aschner,<sup>7</sup> Lambert and Miller,<sup>8</sup> and Schlueter and Weidlein<sup>1</sup> reported unsuccessful attempts to form abscesses by intrabronchial

7. Aschner, P. W.: The Pathology of Lung Suppuration, Ann. Surg. 75: 321, 1922.

8. Lambert, A. V. S., and Miller, J. A.: Abscess of Lung, Arch. Surg. 8:446 (Jan.) 1924.

injections. Holman<sup>9</sup> attempted, without success, to cause abscesses in dogs by placing infected bullets in the lungs through thoracostomy wounds.

### THE PRODUCTION OF PULMONARY ABSCESSES WITH ORGANISMS OBTAINED FROM CHRONIC SINUS INFECTIONS

Following the foregoing unsuccessful attempts to develop pulmonary abscesses in dogs, Dr. Crowe suggested that a new series of experiments be carried out in dogs, in which the starting point should be the establishment of suppuration in the frontal sinuses.

Accordingly, in each of a series of eight dogs, a small trephine opening was made through a short incision over the frontal sinuses; foreign bodies consisting of bits of bone and gauze impregnated with agar were introduced, and the fascia and skin were closed with silk. The wounds healed promptly and were allowed to remain so for about two weeks. Infectious material in the form of scrapings from pyorrheal cavities was then introduced into these sinuses through a needle. Fulminating acute sinusitis followed in all cases, resulting in the spontaneous establishment of a fistula through some point in the operative wound. After a few days, the acute phases of the infection subsided, but chronic sinusitis remained, with a discharge to the exterior persisting in some instances for three or four months.

After four to six weeks of suppuration, each of the eight dogs was given a mild ether anesthesia, and a small pledget of cotton, thoroughly inoculated with the pus from the discharging sinus, was placed by means of a bronchoscope in a secondary bronchus. Of the eight animals thus treated, five developed a clinical picture of pulmonary abscess, characterized by general malaise, loss of appetite, fever, cough, expectoration and a progressive x-ray shadow limited to one lobe. Postmortem examination of the lungs showed in each case an acute process limited to one lobe, and distinguished by necrosis of tissue, liquefaction and the formation of a cavity. Death in each case was the result of extension of the cavity to the edge of the lung and perforation into the pleural cavity (figs. 1, 2, 3, 4, 5 and 6).

Bacteriologic examination of the lungs and pleural fluid in all cases revealed mixed infections; the infecting organisms included staphylococci; streptococci; thick rounded gram-positive bacilli, sometimes resembling diplococci; large gram-positive, slightly motile, spore-bearing bacilli, which grew anaerobically better than aerobically, and spirochetes. On examination of the frontal sinuses at this time, all these organisms, including the spirochetes, were recovered.

---

9. Holman, E.; Chandler, L. R., and Cooley, C. L.: Experimental Studies in Pulmonary Suppuration, *Surg. Gynec. Obst.* **44**:328, 1927.

PROTOCOL 1.—Dog S-5. Chronic frontal sinusitis; pulmonary abscess.

*First Operation.*—Implantation of foreign body in frontal sinus.

March 2: Morphine, 0.015 Gm. Ether inhalation. Right frontal sinus opened. Foreign bodies of bone, bits of gauze and agar placed in sinus. Fascia and skin closed with silk.

March 7: Wound healing. Stitches out.

March 15: Wound healed by first intention. Dog well.

*Second Operation.*—Inoculation of frontal sinus.

Fig. 1.—Early stage in the development of an abscess in a dog's lung. As the necrosis of tissue proceeds, all the small cavities coalesce to form a single large cavity.

March 15: Morphine, 0.03 Gm. A saline suspension of scrapings from pyorrheal cavities in man is injected through a needle into the frontal sinus.

March 17: Marked swelling about right side of scalp, face and right eye. Marked tenderness and fluctuation of soft tissues overlying sinus. Wound not yet discharging. Dog does not appear sick. Temperature by rectum, 103.5 F. (normal for dog from 102 to 102.5 F. by rectum).

March 20: Wound broken open at lower end; discharging thick, brown, foul pus. Dog active, however. Taking food. Temperature, 102.5 F. by rectum.

April 24: Sinus still discharging. Dog active. Temperature, 102.5 F.

*Third Operation.*—Implantation of pus from sinus into bronchus.

April 24: Morphine, 0.015 Gm. Ether inhalation. A firmly rolled cotton pledget (about 3 to 4 mm. in diameter) is inoculated with pus expressed from the frontal sinus and placed, by means of a bronchoscope, into one of the secondary bronchi of the left lower lobe. Small silver clips attached to the cotton pledget serve to identify the position of the plug in x-ray picture (fig. 2).

April 27: Animal appears well. Takes food normally. No discharge from nostrils or eyes. Temperature, 103.0 F. (by rectum). X-ray picture shows cotton plug in place with a small area of increased density about it.

Fig. 2 (dog S-5).—Roentgenogram of dog's lung taken immediately after the introduction into the left lower bronchus of a cotton plug inoculated with pus from a chronically suppurating frontal sinus. Silver clips (indicated by arrows) show the position of the plug (protocol 1).

April 28: Listless today. Refuses food. Has occasional gagging cough. No discharge from nose or eyes. Temperature, 104.0 F. by rectum. X-ray pictures show the cotton plug still in place and with a much increased area of density about it.

April 29: Quite sick today. Listless, refuses food, coarse rattling cough with expectoration of slightly blood-tinged mucopus. Eyes and nose dry. Temperature, 105.2 F. (by rectum). X-ray pictures show the plug still in place in the bronchus, marked consolidation of the entire lower lobe and a definite central cavity (fig. 3). Bronchoscopic examination shows a considerable amount of slightly blood tinged mucopus coming from the left lower bronchus.

April 30: Death.

*Autopsy.*—Left pleural cavity filled with thin serosanguinous, moderately purulent fluid. A smaller amount of similar fluid was in the right pleural cavity. All lobes were normal in appearance, and contained air, except the left lower lobe. This was about twice the normal size, dusky reddish blue, completely atelectatic and rather "rubbery" in consistency, although lacking in elasticity. Section of this lobe (fig. 4) revealed a pulmonary abscess cavity, approximately 2 to 3 cm. in diameter, communicating with the bronchus and filled with a thick, glossy, slightly blood-tinged mucopus in which was found the plug used for inoculation. The cavity extended to the medial surface of the lobe where it had perforated into

Fig. 3 (dog S-5).—Same lung as in figure 2, six days later. There is consolidation of the greater part of the left lower lobe, which has developed centrifugally from the hilum. In the center of the lobe is a large cavity in which the silver clips may be seen.

the pleura, producing empyema. Communicating with this large cavity were several smaller cavities. The parenchyma surrounding these cavities was everywhere involved in a hemorrhagic consolidation (fig. 5).

*Bacteriology.*—Culture 1 (blood-agar plate): Small, clear colonies the size of a pinpoint after four days. Moderately hemolytic. Microscopic examination—small, gram-positive cocci in chains of from 3 to 8. Culture 2 (blood-agar plate): Large, white, confluent colonies; nonhemolytic colonies after four days. Microscopic examination—thick, bluntly rounded, gram-positive, nonmotile bacilli. Culture 3 (Sabanos' medium): Discrete, white colonies, 0.5 mm. in diameter.

Microscopic examination—large, gram-positive, motile bacilli, some of which contained terminal spores and vacuoles. Culture 4 (anaerobic culture in milk): Much gas with foul odor. Microscopic examination—fresh and stained specimens, resembled exactly those organisms found in culture 3.

Dark-field examination showed cocci; blunt, rounded, nonmotile bacilli; much larger mobile bacilli having terminal spores; many spirochetes.

The occurrence of pulmonary abscesses in five of the eight dogs in this series contrasts sharply with the uniform failure to produce abscesses which marked all previous experiments, and indicates that *the*

Fig 4 (dog S-5).—Lung containing large abscess which communicates directly with a major bronchus (protocol 1).

*chronically suppurating frontal sinuses in these animals contributed in some way toward the formation of the lesions.* Actually, there were present in these experiments four possible etiologic factors, any one or more of which may have been essential; namely, (1) the effect of the chronic sinusitis in reducing the resistance of the host to new bacterial invaders; (2) the effect of the chronic suppuration in increasing the virulence of the organisms for the host; (3) the action of the spirochetes; (4) the partial or complete obstruction of the bronchus for a period of time by the cotton plug used to carry the organisms into the bronchi.

To determine which of these four possible factors were essential and which incidental in the production of pulmonary abscesses, further experiments were carried out in which the rôle of each of the factors was studied in turn. These experiments and the deductions gained from them are as follows.

Fig. 5 (dog S-5).—Photomicrograph showing congestion and consolidation in the parenchyma, with walling off of the actual cavity of the abscess (protocol 1).

#### THE EFFECT OF THE CHRONIC SINUSITIS ON THE HOST

It will be noted that each of the animals in which abscesses were obtained had been suffering for weeks with a chronic abscess of the frontal sinus. Was a reduced resistance on the part of the host, the result of long-standing antecedent sepsis, the essential factor in the production of the abscesses?

To determine this point, four healthy dogs were selected for experiment. Cotton pledgets, inoculated with pus coming from the frontal sinuses of the three dogs which had survived the first group of experiments, were placed in secondary bronchi of these healthy dogs. In three of the dogs, abscess of the lung developed, which were in all major respects identical with the abscess of the original dogs. It was therefore evident that the chronically suppurating sinus did not exert

Fig. 6 (dog S-4).—Pulmonary abscess produced by the introduction into a bronchus of cotton carrying pus from a chronically infected frontal sinus of a dog.

any essential etiologic influence on the host, but rather alone on the invading organism.

#### THE EFFECT OF CHRONIC SINUSITIS ON THE INVADING ORGANISM

For the study of this effect, two series of experiments were proposed. In the first, fresh stock cultures of *Staphylococcus aureus* on

cotton pledgets were introduced directly into the bronchi of dogs; in the second, staphylococci were passed through an incubation period in a suppurating sinus before they were similarly introduced into the dogs' bronchi.

*Bronchial Inoculation with Fresh Cultures of Staphylococcus aureus.*—Fresh cultures of virulent *Staphylococcus aureus* on cotton pledgets were introduced by the usual technic into the secondary bronchi of four dogs. These infected pledgets remained in place for 5, 7, 10 and 16 days, respectively. All the dogs were sick to a greater or less degree during

Fig. 7 (dog S-18).—Roentgenogram taken eighteen days after introduction into a bronchus of a cotton plug heavily inoculated with *Staphylococcus aureus*; the plug was dislodged and coughed out just before this picture was taken. Note the massive consolidation limited to the left lower lobe (protocol 2).

these periods, and all showed x-ray evidences of pulmonary congestion or consolidation in the affected lobes. But at no time in any dog was there x-ray evidence of a cavity, and no dog died as a result of the procedure. These lungs, when examined after the animals were killed, showed marked congestion and later consolidation, limited to one lobe, and the whole clinical and pathologic picture strikingly resembled that of lobar pneumonia in man.

PROTOCOL 2.—Dog S-18. *Staphylococcus aureus* (stock strain) into bronchus on cotton plug; bronchial obstruction (16 days); no abscess; recovery.

March 4: Morphine, 0.015 Gm. Ether anesthesia. Operation. Cotton plug about 3 mm. in diameter tightly rolled and inoculated heavily with organisms from an eighteen hour culture of *Staphylococcus aureus* (stock strain). Firmly packed into a secondary bronchus of the left lower lobe through a bronchoscope.

March 9: Indisposed. Temperature by rectum 103 F. (normal rectal temperature for dogs from 102 to 102.5 F.). No cough. X-ray pictures show a shadow near the hilum of the left lower lobe. Cotton pledget still in place.

March 12: Marked malaise. Temperature, 104.5 F. (by rectum). Persistent dry, hacking cough. X-ray pictures indicate increased area of consolidation. Cotton plug still in place.

Fig. 8 (dog S-18).—Gross section of the left lower lobe. There is massive white consolidation involving almost the entire lobe, but not evidence of liquefaction of tissue or the formation of a cavity. The picture suggests a lobar pneumonia.

March 19: Dog appears somewhat better today. Severe gagging cough persists—still not very productive. Temperature, 103.5 F. X-ray observations are essentially the same as on March 17. Plug still in place.

March 22: Animal much better today. Active. Not much cough. Temperature, 103 F. (by rectum). X-ray pictures show the cotton plug to have been coughed out. Area of consolidation is slightly less dense than on last examination (fig. 7). Animal killed.

*Autopsy.*—Both pleurae dry. No adhesions. Left lower lobe slightly larger than the right, of essentially normal color, but quite firm, almost completely atelectatic. Gross section (fig. 8) revealed a large white area of consolidation almost completely filling the lobe, but no evidence of liquefaction or cavity formation.

Microscopic examination showed the smaller bronchioles and alveoli completely filled with mucus, lymphocytes and large wandering cells which resembled phagocytes. There was considerable increase in fibrous tissue stroma. No evidence of necrosis (fig. 9).

*Bronchial Inoculation with Staphylococcus aureus After Incubation in a Frontal Sinus.*—Fresh dogs were chosen and new sinus infections were developed. The technic followed was the same as that used before.

Fig. 9 (dog S-18).—Photomicrograph of consolidated area shown in figure 8. There is marked cellular infiltration of the alveoli, but no evidence of necrosis of the tissue.

except that in these animals the sinuses were inoculated with pure cultures of *Staphylococcus aureus*. The infections ran the usual course and were allowed to suppurate for from four or six weeks. At the end of this time, cotton pledgets inoculated with pus coming from the sinuses were passed in the manner previously described into the secondary bronchi of six new and normal dogs. Four of these animals

developed abscesses which were, in all essential clinical and anatomic respects, similar to those previously obtained (fig. 10).

The bacteriologic examinations in these experiments were extremely significant. In no case was a pure culture of *Staphylococcus aureus* recovered from the lung or pleural cavity. In each case, mixed infections were found which strikingly resembled those in the original groups of abscesses: the infecting organisms including staphylococci; streptococci; short, thick, blunt-ended, gram-positive, nonmotile bacilli and large motile gram-positive, spore-bearing bacilli, growing better under anaerobic than aerobic conditions. These were essentially the same pyogenic organisms as were recovered from all the preceding pulmonary

Fig. 10 (dog S-7) —Abscess five days after intrabronchial inoculation of lung with material from a chronically suppurating sinus.

abscesses. No spirochetes were found. Of even more interest, perhaps, were the observations in the sinuses which had been inoculated with pure cultures of staphylococcus six or eight weeks before. In not one instance was a pure culture of *Staphylococcus* recovered. In each case, a mixed infection was found containing the same organisms as were recovered from the lungs.

As a result of these experiments, two effects of the chronic sinusitis on the invading organisms are shown: (1) that pure cultures of bacteria placed in the frontal sinuses are quickly converted into mixed infections by secondary invaders, and (2) that these mixed infections are many times more powerful as infecting agents in causing abscesses than are the original pure strains. But it is not clear whether the power of the

mixed infection to induce abscesses depends on the activity of some one of the many organisms present or on the combined interplay of all the organisms present. In cases of tissue necrosis or gangrene occurring in other parts of the body, as for example in noma, mixed infections of bacteria, not unlike those obtained from these lungs, are commonly found; but whether this (mixed) type of bacterial invasion is the cause or the result of the lesion still remains to be determined.

The repeated presence of anaerobic bacteria in both the abscessed lung and the chronically suppurating sinus appears particularly significant. In 1924, Lambert and Miller<sup>1</sup> directed attention to anaerobic organisms as possible etiologic factors in the development of pulmonary abscesses. In eight of the ten cases of pulmonary abscess in man in which they performed operations, direct cultures from the cavities yielded anaerobic organisms only. In the remaining cases, anaerobic bacteria were found along with other organisms. These workers attempted to reproduce abscess of the lung in monkeys by the intratracheal injection of these organisms, but were unsuccessful. Whether or not their failure was due simply to inadequate obstruction of the bronchus subsequent to the inoculation remains to be seen (bronchial obstruction will be discussed later in this paper).

#### THE RÔLE OF THE SPIROCHETES

One of the most noteworthy features of the development of pulmonary abscess in the preceding group of dogs was the complete absence of spirochetes. Careful examination of lungs and pleural fluid by staining and dark-field methods failed to reveal these organisms in any instance, and it is possible to say, therefore, that in the establishment of acute pulmonary abscess by aspiration in dogs, spirochetal infection is not an essential factor.

In 1923, Kline<sup>2</sup> injected into the trachea of rabbits infectious material containing many spirochetes, taken from the carious teeth and lungs of a man who died of pulmonary gangrene, and obtained in two animals localized gangrene of the lung. Smith<sup>3</sup> injected into the trachea of mice, guinea-pigs and rabbits, sputum from abscesses of the human lung, containing great numbers of spirochetes, and obtained abscesses in 20 per cent of his animals. Since then, other clinical workers have demonstrated spirochetes in the lungs and sputum of patients with pulmonary abscesses, and there has been a growing tendency to ascribe to spirochetes the essential etiologic rôle in the development of these lesions.

In all these studies, however, the fact has been lost sight of that the spirochetes were always found in company with mixed bacterial infections, and the possibility that these latter organisms may have been

the true etiologic factor has been ignored. The mere presence of the spirochetes in abscess of the lung has been taken *ipso facto* as proof that they were the cause of the abscess. Two bits of experimental work, however, suggest that this may not be so. Kline,<sup>2</sup> in other studies on gangrene, working on guinea-pigs with the same type of infections as before, transmitted gangrenous abscesses of the groin from one guinea-pig to another to the thirty-sixth generation. While spirochetes, together with other organisms, were present in great numbers at the time of the original inoculation and during the first generations they early began to diminish in numbers and were never found after the twelfth generation, although the virulence of the infection and the destructive nature of the lesions increased progressively. In this connection, the studies of Tunncliffe<sup>10</sup> are unique, in that this investigator worked with pure strains of spirochetes which had been isolated from a severe case of Vincent's angina. When these organisms were injected in huge amounts, subcutaneously, intraperitoneally, under the mucous membranes of the mouth and intravenously, in rats, guinea-pigs, rabbits, pigeons and dogs, not a single significant suppurative lesion was produced.

It is evident, therefore, from these experiments that spirochetal infection is not an essential etiologic factor in the production of these acute abscesses, although it is not inconceivable that spirochetes will be found to play a rôle in the development of chronicity in the lesions.

#### THE SIGNIFICANCE OF BRONCHIAL OBSTRUCTION

In each of the three groups of experiments thus far quoted, there have been a number of successful attempts to induce pulmonary abscesses and a number of failures, notwithstanding that, within the limits of each group, all the experiments have been carried out with the same technic, and, so far as possible, under identical conditions. In all of those resulting in abscess, however, there has been one common factor, namely, a high degree of bronchial obstruction for a more or less prolonged period. It seems certain, then, that this factor is of prime importance in the production of pulmonary abscess by aspiration in dogs.

Following the introduction of a cotton plug inoculated with truly pathogenic organisms into the bronchus of a dog, a characteristic clinical course ensues. The dog becomes listless; loses his appetite; has a slightly elevated temperature, and develops a dry unproductive cough. Roentgenograms show an increasingly dense shadow throughout the affected lobe. Examined at this time, the affected lobe appears larger

10. Tunncliffe, R.: Further Studies on Fusiform Bacilli and Spirillae, J. Infect. Dis. 8:316 and 321, 1911.

than normal, is dark reddish-blue, is rubbery in consistency and drips blood when sectioned (fig. 11); microscopically, the bronchi are filled with mucus, and the alveoli with leukocytes (fig. 12). If the plug remains in place after the fourth or fifth day, signs of general malaise increase greatly, appetite is completely lost, high fever develops, the cough becomes more severe, changes shown by the x-ray pictures become more striking and the dog eventually succumbs to the disease (protocol 1). If, however, the plug is dislodged

Fig. 11 (dog S-11).—Massive atelectasis of the left lower lobe three days after obstruction of the major bronchus by an infected cotton plug.

and coughed out on the second, third or fourth day (that is, before the graver group of symptoms develops), a remarkable retrogression of symptoms is seen. Immediately after the bronchial obstruction has been released, the cough becomes much aggravated, gagging in character and productive of much thick tenacious mucus. Within twenty-four hours, a marked improvement is seen in the animal's condition, its activity is increased, its appetite is improved, its temperature approaches normal and the x-ray shadows are of definitely diminished density. The cough and expectoration of thick mucus may persist for

three or four days, but at the end of this time the animal is essentially normal clinically and according to x-ray pictures, and examination of the lungs does not reveal any significant pathologic change. The following case is typical:

PROTOCOL 3.—Dog S-15. Implantation of infected plug into bronchus; massive atelectasis of lungs; plug coughed out; recovery.

Fig. 12 (dog S-11).—Photomicrograph of the atelectatic lung shown in figure 11. The bronchi are filled with mucus and the alveolus with leukocytes. The picture is not unlike an early stage in lobar pneumonia.

Aug. 25: Operation—morphine, 0.015 Gm. Ether inhalation. Small tightly rolled cotton plug inoculated with pus from a discharging frontal sinus (dog S-1) tightly packed into secondary bronchus, right lower lobe.

Aug. 27: Dog does not appear sick. Takes food well. No cough. Rectal temperature, 103 F. (normal rectal temperature for dogs from 102 to 102.5 F.). X-ray pictures show slight shadow in region of right lower lobe. Plug in place.

Aug. 28: Dog appears sick today. Listless. No appetite. Temperature, 103.5 F. (by rectum), but no cough. No discharge from nostrils or eyes. X-ray

pictures indicate marked consolidation of the entire right lower lobe (fig. 13). Bronchial obstruction still present.

Aug. 30: Dog has a coarse gagging cough today and is expectorating small amounts of tenacious mucus. Still rather sick. Temperature, 103.5 F. (by rectum). X-ray pictures still show considerable consolidation of right lower lobe, but the obstructing plug has been coughed out.

Aug. 31: Dog is much better today, although still coughing. Temperature is only 102.5 F., and dog is taking food. X-ray shadow of the right lower lobe is much less dense than before.

Sept. 1: Dog practically well. Is active and eating well. Has slight persistent cough. No discharge from nostrils or eyes. Temperature, 102.5 F. (by rectum). X-ray pictures show almost complete return to normal (fig. 14).

Fig. 13 (dog S-15).—Roentgenogram showing massive atelectasis of right lower lobe, three days after implantation into a bronchus of an infected cotton plug (protocol 3).

Sept. 8: Dog entirely well. X-ray pictures negative. Dog killed. Pleurae dry. Lungs normal.

The lesions just described appear to be true postoperative massive atelectases of the lungs of dogs, resembling closely the analogous condition in man. These observations are in agreement with the experiments of Coryllos and Birnbaum<sup>11</sup> who contend that postoperative massive

11. Coryllos, P. N., and Birnbaum, G. L.: Obstructive Massive Atelectasis of the Lung, *Arch. Surg.* **16**:501 (Feb.) 1928; Lobar Pneumonia Considered as a Pneumonic Massive Atelectasis of the Lung, *Bull. New York Acad. Med.* **4**:384. 1928.

atelectasis of the lung is always the result of bronchial obstruction. These experiments indicate that in dogs there is a close etiologic relationship between postoperative massive atelectasis and postoperative pulmonary abscess.

When an infectious mucous plug is present in a bronchus, the type of pulmonary lesion resulting depends, apparently, on two factors: (1) the pathogenicity of the organisms on the plug, and (2) the extent of the bronchial obstruction. If the mucous plug is coughed out and the bronchial obstruction relieved during the early days of the lesion, the pathologic condition rapidly clears up, regardless of the type of infection on the plug, and one sees the typical picture of a transient massive

Fig. 14 (dog S-15).—Roentgenogram taken four days later than that in figure 13, and three days after obstructing foreign body had been coughed out of bronchus. Lung was normal when examined several days after this picture was taken.

atelectasis. If, on the other hand, the bronchial obstruction remains for a longer period, three different clinical courses are open, dependent on the presence and degree of pathogenicity of the organisms found in the mucous plug. If the plug is sterile, atelectasis persists indefinitely, accompanied by progressive fibrosis and shrinkage of the lung. If the organisms are purely pyogenic, a low grade pneumonitis results, involving all of a single lobe, and not unlike lobar pneumonia. A typical example of such a lesion has been described (protocol 2), and similar results have been obtained by Coryllos and Birnbaum.<sup>11</sup> Finally, if the mucous plug remains in place but carries putrefactive organisms or

those tending to produce liquefaction of tissues and cavitation, abscess of the lung develops (protocol 1). That bronchial obstruction, however, is a necessary factor in the development of these lesions in dogs is further shown by the following experiments:

Protocols 4 and 5.—Dog S-26. Right frontal sinus infected with *Staphylococcus aureus*; chronic suppuration for six weeks; repeated inoculation of trachea and bronchi with pus from sinus; no pathologic lesions.

Dog A-2: Right frontal sinus infected with scrapings from pyorrheal cavities in man; chronic suppuration for six weeks; repeated inoculation of trachea and bronchi with pus from sinus; no pathologic lesions.

Two dogs were used which had had chronic suppuration of the frontal sinuses for over six weeks. One of them had been infected with *Staphylococcus aureus*, the other with scrapings from pyorrheal cavities in man. Material from each of these sinuses had been used to produce abscesses in other dogs and had, therefore, a proved pathogenicity.

Every other day, over a period of six weeks, under light ether anesthesia, and after the mucous membranes of the trachea and the larger bronchi on the left side had been mildly abraded with a small bit of gauze through a bronchoscope, cotton pledgets heavily inoculated with pus from the discharging frontal sinuses were rubbed over the abraded surfaces and then removed. In neither dog did there develop any clinical or x-ray evidence of pulmonary suppuration, and when they were killed evidence of such a lesion was not found.

It is evident from these experiments that, at least in dogs, bronchial obstruction is a prime etiologic factor in the production of the aspiratory type of pulmonary abscess.

#### THE PRODUCTION OF PULMONARY ABSCESES WITH ORGANISMS OBTAINED FROM DISEASED TEETH AND GUMS

Two of the ten original abscesses reported in an earlier communication<sup>1</sup> resulted from the inoculation of cotton plugs with material scraped from the alveolar margins of patients suffering with dental caries and pyorrhea, which were introduced directly, without other preparation, into the bronchi of the dogs. Clinically and according to the x-ray pictures, the courses of these two animals were essentially the same as those of animals developing abscesses after inoculation of the bronchi with material from chronically diseased frontal sinuses; and the abscesses obtained did not differ essentially from those of the other group (fig. 15). There was a high degree of obstruction in the bronchus leading to the affected lobe in each case. Examination revealed mixed bacterial infection and numerous spirochetes in both lesions.

These two experiments indicate that chronic infections found about decaying teeth and diseased gums (as well as in suppurating accessory sinuses) have a special pathogenicity for production of pulmonary abscesses in dogs. In this respect, the results

agree with the work of Smith<sup>3</sup> who obtained abscesses in the lungs of the smaller laboratory animals by injecting into their trachea scrapings from the teeth and gums of patients suffering with dental caries and pyorrhea. The reason for Smith's failure to induce abscesses in dogs is not clear, but probably it was due to the absence of bronchial obstruction following the introduction of his organisms into the lung.

#### REVIEW

This paper describes the experimental production of pulmonary abscess in the dog by the introduction of infected foreign bodies into

Fig. 15 (dog S-1).—Abscess produced experimentally in a dog's lung by the introduction into a bronchus, on a piece of cotton, of material from human carious teeth and diseased gums.

the bronchi. In addition, it is a study of the etiologic relationship between postoperative abscess of the lung and chronic focal infections of the upper respiratory tract.

Early attempts, here reported, to induce pulmonary abscess in dogs were unsuccessful. In later experiments, chronic suppuration of the frontal sinuses was produced in dogs, and the pus obtained from these lesions was used to inoculate cotton pledgets which were then introduced into the dogs' bronchi through a bronchoscope. By this means, acute pulmonary abscesses were repeatedly obtained. Similar experiments,

carried out with material from carious teeth and diseased gums in human beings likewise resulted in abscesses.

The bacteria obtained from these abscessed lungs included strains of ordinary pyogenic organisms, spore-bearing anaerobic organisms and spirochetes. Subsequent experiments showed that spirochetes, however, were not an essential factor in the development of this acute aspiratory type of abscess in dogs, although it remains possible that they may play a rôle in the development of chronicity in these lesions. It is significant that the abscesses all follow the introduction of "mixed" infection into the lungs, for attempts to reproduce the lesions by substituting a single strain of organisms in place of the mixed strains resulted only in a diffuse pneumonitis, limited to one lobe, greatly resembling a lobar pneumonia, but not showing any tendency to liquefaction or the formation of a cavity. Whether a combination of the organisms working together in mixed culture is the essential factor, or whether some one variety, such as the anaerobic bacteria, is the etiologic agent, has not yet been determined. At present, the striking and apparently fundamental observation is that the active agent causing pulmonary abscess is present in pus draining from chronic focal infections about the upper respiratory tract.

Bronchial obstruction for several days following the introduction of even pathogenic bacterial agents proved to be indispensable to the development of the aspiratory type of pulmonary abscess in dogs. The experiments also afford interesting evidence of a close etiologic relationship between postoperative massive atelectasis and lobar pneumonia; for instance, when the bronchus of a dog becomes occluded by a foreign body, typical massive atelectasis develops. If the foreign body is coughed out before two or even three days, the massive atelectasis clears up. If, however, the foreign body remains in place, one of three events follows, depending on the presence and pathogenicity of bacteria on the obstructing object. If the foreign body is sterile, atelectasis persists indefinitely, accompanied by a progressive fibrosis and shrinkage of the lung; if the foreign body carries simple pyogenic organisms, a diffuse pneumonitis develops, limited to one lobe, resembling lobar pneumonia in man; if the foreign body carries putrefactive organisms or those tending to cause liquefaction and cavitation in tissues, abscess develops. But no matter what organisms are introduced, obstruction of the bronchus is essential in the production of pulmonary abscess in a dog.

### CONCLUSIONS

1. Acute pulmonary abscesses may be induced experimentally in dogs by the introduction of infected foreign bodies into the bronchi.

2. The bacteria obtained from chronically suppurating nasal sinuses and from the mouths of persons suffering from dental caries and pyorrhea are especially pathogenic for the production of pulmonary abscess in dogs. Spirochetes are not necessary to the development of these lesions. Anaerobes are usually present, but their importance has not been definitely determined.

3. Obstruction to free bronchial drainage for several days after the introduction of infectious material into a bronchus is necessary to the development of pulmonary abscesses in dogs. A close etiologic relationship between postoperative massive atelectasis and postoperative pulmonary abscess suggests itself.

## BILATERAL CERVICAL RIB

CLINICAL AND EXPERIMENTAL OBSERVATIONS ON A CASE \*

IGNAZ OJENICK

Circulatory disturbances are comparatively rare symptoms in cases of cervical rib. According to the figures published by Adson and Coffey,<sup>1</sup> they were present in seventeen of 303 cases (5.6 per cent). Four of these seventeen occurred among 100 patients who presented only mild complaints which did not necessitate surgical intervention, while the other thirteen belonged to a group of thirty-six patients on whom operation had been performed. Thus circulatory disturbances were nine times as frequent in those patients with characteristic symptoms. Other symptoms also occurred more often in the group subjected to operation, the figures for muscular atrophy being 12 and 22 per cent for the two groups. The greater increase in the incidence of circulatory disturbances seems to suggest their importance as an indication for surgical treatment.

These vascular phenomena vary from a slight discoloration of the hand to gangrene of one or more fingers. In his monograph on cervical ribs, Streissler<sup>2</sup> ascribed them to compression of the subclavian artery and vein by the cervical rib, resulting in a partial or complete, temporary or continuous impairment of the venous flow and especially of the arterial supply of the upper extremity causing changes in the pulse, thrombosis of the arteries, the formation of an aneurysm and trophic changes. In the same article, he claimed that there is no doubt that the pressure of the cervical rib on the vessels plays an important part, for no circulatory disturbances occur unless the artery has to run over the rib. However, special conditions must supervene to produce such phenomena, as the mere presence of a cervical rib need not necessarily cause any symptoms. Repeated minor traumas caused by normal and forced inspirations, particular movements of the arm, pressure of garments or loads carried on the shoulder and many other circumstances may cause the onset of symptoms at any age. Gordon<sup>3</sup> explained the effect on the artery not only by pressure but by a disturbance of the vasomotor nerves. Adson<sup>1</sup> remarked that one can demonstrate how the scalenus muscle compresses the subclavian artery from one half to one third of its normal size, the pressure being transmitted posteriorly and laterally to the lower and middle trunks of the brachial plexus as

---

2. Streissler, E.: *Die Halsrippen*, *Ergebn. d. Chir. u. Orthop.* **5**:280, 1913.

3. Gordon, T. E.: *A Case of Cervical Rib*, *Brit. M. J.* **1**: (June 8) 1909.

they lie on the cervical rib. The degree of compression depends directly on the width of the scalenus anticus attachment and the angle of the cervical rib which determine the width of the space between the lateral portion of the muscle and the rib. The circulatory changes are caused by constriction of the subclavian artery or subclavian vein, obstruction of the radial and ulnar arteries by emboli from thrombosis at the site of constriction or possibly by disturbance of the sympathetic innervation. Adson is convinced that tenotomy of the scalenus anticus muscle at its insertion is preferable to the resection of the cervical rib since it immediately relieves the subclavian artery and the brachial plexus from pressure and irritation.

The case presented here is one of bilateral cervical rib with unilateral symptoms in which this simple division of the scalenus anticus was carried out. Although this procedure immediately freed the subclavian artery from pressure and permitted it to slide downward along the cervical rib, no prompt relief from the circulatory disturbances was obtained since the vessel was found to be thrombosed.

During the patient's stay in the hospital a thorough investigation of the circulation under various conditions was made. Plethysmograms, sphygmograms and skin temperatures furnished objective data, presenting excellent material for comparative study of the affected and the normal sides.

#### REPORT OF CASE

*History.*—Nelly P., aged 24, single, a telephone operator, was admitted to the Peter Bent Brigham Hospital on March 8, 1928, complaining of occasional discoloration and numbness of the four ulnar fingers of the left hand. She was referred by Dr. D. L. Lynch of Boston. The family and past histories were irrelevant.

*Discoloration of Fingers:* About three and a half to four months preceding admission, the patient noticed, while going home from her work on a cold night, that the little finger of her left hand had turned numb and white, remaining so for about ten minutes. The condition recurred occasionally until some weeks after the onset all the fingers of the left hand except the thumb turned white and numb. This happened especially when it was very cold and would last twenty minutes at the utmost. About three months before admission, she noticed that the left arm would tire easily. Her hand would often turn white and cold, when using it strenuously and especially when working overhead. After resting it a few minutes the normal color would reappear and she could continue her work. The same discoloration would manifest itself when she was engaged in housework, such as making up beds, or while washing her hair, particularly when she reached at the back of her head.

*Fatigue and Pain in the Left Shoulder and Left Arm:* Two months before, while on evening duty, the patient noticed that her left arm felt extremely tired, more so than it had ever done. She could not put the plugs into the switchboard, especially when they were overhead, and was forced to give up her work ten minutes ahead of time. That night she noticed a fairly severe pain in the left shoulder radiating down the arm to her fingers. In the morning the pain had gone. She continued doing her work for two days, experiencing the same difficulty,

particularly in work overhead. Since then, on the advice of her physicians, she had not returned to her work. The pain came back occasionally during one week only, but the fatigue continually returned after the slightest exertion.

During the last month the left forearm had gradually grown smaller. The patient had to readjust the strap of her wrist watch a couple of times.

Loss of Sensation of Temperature-Stimuli: One week before admission, the patient put her left hand into cold water, but thought that it was warm. This happened only once.

There was no change in her condition notwithstanding the two months' period of rest.

*Examination.*—The results of the physical examination were negative except for the following observations: There was a definite sinus irregularity with a faint systolic bruit at the base of the heart, but no enlargement. The left pupil was larger than the right, but both reacted normally.

*Comparative Examination of the Right and Left Arms:* No difference in color was noted at the first examination. During the observation a marked pallor of the left hand and the fingers was frequently seen, especially when the patient went out into the open air, but also, without any apparent cause while she was resting in bed. At times the left hand became cyanosed and remained so for a whole day. There were no trophic disturbances of the skin and no edema. The left upper arm and forearm were decidedly smaller. There was no difference in length.

TABLE 1.—Measurements of Right and Left Arms

	Right, Inches	Left, Inches
Circumference of upper arm.....	9 $\frac{1}{4}$	8 $\frac{1}{4}$
Circumference of forearm just below the elbow.....	9 $\frac{1}{2}$	8 $\frac{1}{2}$
Circumference of wrist.....	6 $\frac{1}{4}$	6
Circumference of hand around the palm.....	7 $\frac{1}{2}$	7 $\frac{1}{4}$

The brachial, radial and ulnar pulses were distinct on the right side, but absent on the left, although the brachial artery was easily palpated all along the internal bicipital sulcus down to the cubital fossa, while the radial and the ulnar vessels were not felt. In the right arm, the systolic blood pressure was 115, the diastolic 75; none obtained in the left arm. The muscles of the shoulder girdle were equal on both sides. All the other muscles of the upper part of the arm, forearm and hand showed less power on the left than on the right. No sensory disturbances were made out at the first examination. However, during the periods of discoloration, sensation was impaired in the white or bluish areas. The reflexes were about equal on both sides. Electric examination revealed normal and equal reaction on direct and indirect faradic and galvanic stimulation. Examination of the supraclavicular region revealed a very marked bony resistance on the left side. The brachial plexus ran over this bony prominence, as was evidenced by the typical pain radiating down to the lateral side of the scapular region and along the ulnar side of the whole arm on pressure. A similar but less marked resistance was found in the right supraclavicular fossa. The right brachial plexus was also felt. While no arterial pulse was noticed on the left side, the pulsating right subclavian artery was easily palpated. In no position of the left arm could a pulse in any of the arteries be felt nor could a pain similar to pressure pain on the brachial plexus be elicited. The same applied to the right side, where no impairment of the blood flow nor irritation of the plexus could be produced by movement of the arm. X-ray films of both shoulders showed bilateral cervical ribs, each articulating

with the first thoracic rib just behind the clavicle. The right cervical rib appeared to go straight anteriorly; the left one was thinner and had a more oblique direction (fig. 1).

From the history and this preliminary examination it appears that the atrophy and the functional impairment were not restricted to a particular group of muscles but involved the whole left arm. Sensory disturbances only occurred simultaneously with vascular phenomena, both being equally transitory. Their distribution was not of the plexus

Fig. 1.—Bilateral cervical ribs, each articulating with the first rib just behind the clavicle.

nor of the peripheral type. Although the roentgenogram confirmed the presence of bilateral cervical ribs, only the left one produced symptoms, these being solely circulatory. The condition indicated a serious impairment of the arterial blood supply to the whole arm, especially so to its peripheral parts.

The influence of cold and heat on the circulation in the two arms was examined.

1. When the patient held both hands quietly, without movement, in cold tap-water for ten minutes, differences in color or temperature between the left and right sides did not result. Only after drying her hands the finger-nails of the left hand turned definitely cyanotic, resuming a normal color after a few minutes.

2 When both hands were washed in cold water, a pallor and numbness of the whole left hand developed, most marked in the four fingers

3 No difference was observed after both hands were held in warm water

Plethysmograms of both hands were recorded simultaneously with Mackenzie's polygraph. The patient held in each hand a stiff rubber bulb ending in a small tube, by bending her fingers over it without squeezing. The whole hand with the bulb was wrapped up tightly with a wide flannel bandage leaving the tube-ending free (Wiersma's method<sup>4</sup>). This bulb was connected by means of an intermediary glass and a stiff rubber tube with the tambour of the polygraph. An increase in volume of the hand produced some pressure on the rubber bulb and the resulting displacement of the air in the tambour raised the lever; a decrease in volume lowered the lever (fig. 2). A fair tracing was obtained on the right; no plethysmogram was secured on the left, indicating that no measurable changes in volume were present. This test was repeated with a similar result.

Comparative studies of the circulation in the two arms under various conditions were frequently made with Benedict's<sup>6</sup> thermoelectric method.

The temperatures of the skin were taken at rest, while covered or uncovered, after cooling without and with exercise, after slight movements, as undressing, and after different kinds of strenuous exercise of the arms or hands. Closing and opening both hands, thrusting both arms up and down, pulling herself up and down in bed by means of an iron crossbar overhead were chosen as regular exercise and were continued until exhaustion.

These records of the temperature of the skin permit the following deductions:

1 When there was no loss of heat, the arms being covered, the blood supply of the left hand was relatively sufficient, as evidenced by only slight differences in temperature between the two sides (fig. 4). When there was loss of heat, both arms being uncovered, the blood supply of the left hand was inadequate, as shown by its considerably lower temperature as compared with the right hand (fig. 3).

2 Symmetrical cooling of the hands by holding them quietly under tap-water or by an alcohol rub resulted in a greater fall of the higher temperature on the right side. The effect of equal vasoconstriction on

both sides necessarily resulted in a greater diminution of the skin temperature on the right side as a larger blood supply was shut off. It practically wiped out the difference between the two sides. That the right hand usually was slightly warmer was presumably due to a better circulation in the deeper vessels (fig. 5 *A*).

3. Return to normal after the cooling was stopped was much delayed on the left, due to the inadequate blood supply to the peripheral vessels. The quick rise to the original temperature of the right hand may be attributed to the reflex dilatation of the capillary system after the previ-

Fig. 2.—Showing the two rubber bulbs, the glass and rubber connections and Mackenzie's polygraph with the two tambours and the time recorder.

ous vasoconstriction, which may have occasionally led to a temperature above that at the onset (fig. 5 *A*).

4. Bilateral exercise of the hands or arms led to a diminution of the temperature of the skin of both hands below normal, but much more marked on the left side, which turned very cold, pale, dry and numb (fig. 5 *B* and *C*). If this exercise was started while the capillary system of the skin was dilated, consequently containing an unusually large amount of blood, the decrease might result in a normal temperature. Slight and easy movements as undressing represented sufficient exercise to result in a considerably lower temperature of the left hand.

5. The influence of muscular exercise of the arm on the temperature of the hands was practically none, or hardly noticeable, when the blood

The dotted lines connect the skin temperatures after the patient washed her hands in cold tap-water for five minutes. Note the extreme fall of the temperature of the finger-tips on the left side.

flow was already insufficient at the onset. Under such conditions only prolonged exercise might eventually show its influence, and then solely in the most sensitive parts—the finger-tips.

6. Exercise and cooling combined, washing her hands in running tap-water, resulted in an excessive drop of the skin temperature, particularly of the left hand and consequently in a too extreme deflection of the galvanometer to permit accurate measurements. Even after ten

Fig. 5.—Nelly P., March 26, 1928. Skin temperatures of the right (solid line) and left (broken line) thenar, hypothenar and index finger-pad. *A* shows the decrease of the temperature after cooling both hands in cold tap-water without moving and the consecutive rise. Note the delay in the return to normal temperature on the left side, particularly marked on the index finger-pad. *B* and *C* show the fall of the temperature after exercise of both hands and both arms.

minutes when the temperature had risen considerably, its diminution was still important. Maximum decrease of the right hand was 10.9 C.; on the left side, 18.7 C. (fig. 4).

7. The lesser difference in temperature between symmetrical points of the dorsum of the hands as compared with the volar side was due to

its normally lesser blood supply and cannot be attributed to the fact that the temperatures of the dorsum were systematically taken last (fig. 4). A series recorded in reverse order confirmed this.

*Diagnosis.*—The symptomatology of this case resembled closely that seen in intermittent claudication, the patient usually having no complaint when at rest, provided there was no great loss of heat, while infallible signs of an inadequate peripheral circulation in the left hand appeared as soon as she exercised her arm. The figures obtained in the skin temperature tests as well as the absence of a plethysmogram on the left side confirm the subjective and objective symptoms of an inefficient collateral circulation in the absence of any blood supply through subclavian, brachial, radial and ulnar arteries. A disturbance of the vasomotor nerves need not be considered, as this will never lead to the disappearance of the pulse in as large an artery as the subclavian. No neurologic signs being present, the diagnosis of circulatory disturbances only, due to the left cervical rib, was made.

*Operation.*—Division of the scalenus anticus insertion was performed by Dr. Harvey Cushing, on April 3, 1928, under procaine hydrochloride anesthesia after preliminary injection of morphine-scopolamine. A curvilinear thyroid incision was made followed by division of the outer portion of the sternocleidomastoid muscle; exposure of the subclavian and jugular veins at their junction together with the cervical portion of the thoracic duct; division of the scalenus anticus at the tubercle Lisfranc exposing solidified artery.

The scalenus muscle retracted after division at its point of attachment, showing the artery being unquestionably closely imprisoned by a few dense bands, the extension of the muscular sheath. Very little dissection was necessary to bring the artery into view. As soon as it was completely freed, it was seen to slide down from an unusually high position. Even after dissection of its dense sheath the artery showed scarcely any pulsation, nothing more than a slight heave suggesting a transmitted pulse from its more central portion. Palpation of the outer part where it overlay the cervical rib proved it to be hard and solid, presumably thrombosed. The brachial plexus was felt lying over the palpable rib, being much more superficial than usually.

The operation undertaken with the idea of following Adson's<sup>1</sup> suggestion to relieve the symptoms caused by cervical rib by simple division of the scalenus anticus insertion proves to be a satisfactory procedure as far as freeing the subclavian artery and eventually the brachial plexus from pressure is concerned. That the operation did not result in any immediate improvement of the circulatory disturbances in this case was due to a complete thrombosis of the subclavian vessel. The gradual obliteration of the artery allowed time to establish a collateral circulation by way of the transverse cervical and suprascapular arteries, which, however, proved to be insufficient. The operative observations showed that this artery had to make a much higher and smaller loop as it crossed over the cervical instead of over the first thoracic rib (fig. 6).

Owing to its straight instead of curved form, the cervical rib makes a very small angle with the scalenus anticus. It is readily acknowledged that the subclavian artery is easily traumatized in this narrow passage, the more since the insertion bands of the anterior scalenus prevent its escape from pressure. Instead of a wide triangular area between the anterior scalenus, the middle scalenus and the first rib, only a small irregular space bordered by the anterior scalenus in front and the either curved or straight cervical rib laterally and behind is available for the passing of subclavian artery and brachial plexus, which adds considerably to the danger of compression on particular movements of the shoulder. Another danger arises from the abnormally high and

Fig. 6.—Schematic drawing of the topography of the lower part of the posterior triangle of the neck. The dotted line indicates the position of the subclavian artery in the case reported, showing the high and narrow loop where it crosses over the cervical rib.

narrow loop of the vessel, which favors the origin and the development of circulatory disturbances.

*Postoperative Course.*—The patient made a rapid, uneventful recovery from the operation. On the tenth postoperative day a very feeble radial pulse was felt for the first time, which, however, appeared to be inconstant. No pulsation whatever could be made out in the subclavian, brachial or ulnar arteries. For the following six days there was no change, the pulse being too weak and too irregular to be counted. After that it became gradually stronger, while there was no return of the pulse in the other palpable vessels nor any improvement in the circulation when the patient used her arm.

April 24, 1928: A series of skin temperatures taken after a short rest following slight movements showed equal temperatures of both hands throughout with the exception of the finger-tips on the left side, which were from 0.7 to 1.7 C.

colder than on the right side. After cooling without movement in running tap-water, practically the same temperature was found on both hands, but only the finger-tips of the left side were white. No exercising tests were done to avoid any possible traumatism, which might interfere with canalization or organization of the thrombus.

April 25: The patient was discharged. No further changes were observed in the last week except a further increase in the radial pulse, although no plethysmograms of the left were as yet available.

The patient reported fourteen times between April 25 and Sept. 1, 1928. The most important observations are discussed.

*Subsequent Course.*—May 11: The left hand tired very rapidly, although no more spontaneous discoloration was noticed. Only when the arm was exercised or exposed to cold did the whole hand, more especially the four ulnar fingers, get white and numb. Examination showed the radial pulse to be slightly stronger while the tendency to fatigue appeared to become less pronounced. During strenuous muscular exercise of the upper part of the arm mostly, the pulse disappeared. It took seventy-five seconds before it was again palpable and fully two minutes to regain its original strength. No influence on the radial pulse was observed after cooling while the hands were kept quiet, although the left hand

Fig. 7.—Nelly P., June 12, 1928. Simultaneous plethysmograms of both hands showing a normal curve on the right and an abnormal tracing on the left side.

seemed to be much colder than the right. Skin temperatures showed the left hand to be considerably colder than the right after equal exposure in the room. Cooling in tap-water resulted in practically the same temperature on both sides.

June 12: The patient reported that her left arm was slowly improving. It was getting somewhat stronger. Although she was an expert swimmer she could make but a few strokes, as almost immediately her left arm became tired and her hand turned white, cold and numb.

This was the first time that a plethysmogram of the left hand was obtained (fig. 7). It was very low and lacked all the characteristic sharp angles and salient points of the normal plethysmogram of the right side. No pulse was felt in any of the other arteries.

Owing to the insufficient blood supply, no satisfactory results were obtained with an ordinary plethysmograph. Mackenzie's polygraph was used again, as it has the advantage of recording simultaneously the changes in the plethysmograms of both hands under various circumstances. Furthermore, it can be easily connected and disconnected allowing the arms to move freely and enabling one to keep the pressure in airbulb-tubing-tambour apparatus the same.

June 15: After bending and stretching both arms simultaneously against resistance<sup>7</sup> for one and a half minutes the right plethysmogram was definitely lower and less pointed at the top (fig. 8). It gradually returned to normal in about two minutes. The left tracing presented at first a straight line without any elevation except some tremor-like irregularities which, however, were not synchronous with the pulse. After two minutes a slight trace of a plethysmogram showed, which immediately increased after the hand had been rested comfortably on the thigh. This enlargement appeared to be due to transmission of the femoral pulse, as it was discontinued as soon as the hand was put back on the bed. Four minutes and fifty-two seconds after the exercise was stopped a definite plethysmogram was recorded on the left side. When the experiment was repeated, both arms became tired after the exercise. Both plethysmograms showed to have disappeared, the right one reappearing thirty seconds after the exercise was stopped, but being much

Fig. 8.—Nelly P., June 15, 1928 (experiment 4). Simultaneous plethysmograms of both hands recorded with Mackenzie's polygraph. Tracing 1 shows a normal plethysmogram of the right hand and an abnormal plethysmogram of the left hand; after two minutes' exercise the right was much lower than before exercise, while no plethysmogram was obtained on the left side. Tracing 2 shows the right plethysmogram increased in height while the left began to show; this began about two minutes after the exercise was stopped. Tracing 3 was obtained while the patient was resting the left arm on the thigh, but the tracing was derived from transmission of the pulse of the femoral artery. Tracing 4, taken four minutes and fifty-two seconds after the exercise was stopped, shows that a definite though abnormal plethysmogram was reobtained on the left side.

7. During this exercise the forearm was held in semipronation, allowing the resistance to be exerted alternately against the radius and the ulna to avoid pressure on the blood vessels.

lower than normal. A normal plethysmogram was obtained on the right side after three minutes and four seconds. Only a very slight trace of a pulse wave was seen off and on on the left side during the first minute. It took fourteen minutes and twenty-six seconds before a definite plethysmogram was recorded.

These tracings present objective evidence that muscular exercise of the upper part of the arm resulted in temporarily lowering the blood volume changes in the hands, even of the normal arm. The return to a plethysmogram as recorded before the onset of the exercise was much delayed on the left side. Prolonged exercise leading to fatigue was seen to result in a temporary complete disappearance of the plethysmogram.

A series of experiments was started to investigate further the influence of muscular exercise of the shoulder and upper part of the arm on the circulation of the hand in apparently normal persons. These experiments fully confirmed the observations that the plethysmogram of the hand decreases temporarily as a result of this muscular activity.

Furthermore, there appears to be an inverse relationship between the height of the plethysmogram and the frequency of the pulse which in spite of some slight variations is practically constant (table 2).

Similar variations in height are observed in the plethysmogram according to the amount of pressure exerted on the upper part of the arm by means of air blown into an aircuff of an ordinary blood pressure apparatus (fig. 9). As is illustrated in table 3, the plethysmogram has already decreased in height when the pressure in the cuff is raised to the

diastolic blood pressure. Gradual increase in pressure lowers the plethysmogram until no more tracing is obtained when the pressure in the cuff equals the systolic blood pressure. No influence is observed unless the pressure in the air cuff is well above the venous pressure which leaves only a small range until the relatively low diastolic blood pressure is reached.

Although these changes in the plethysmogram appear to be the same, their cause cannot possibly be identical. Compression leads to venous stasis, dilatation of the veins and of the capillaries and swelling of the

Fig. 9.—M. C., June 21, 1928. Blood pressure 106 systolic and 66 diastolic. Tracing 1 shows plethysmograms recorded during compression of the upper part of the arm and tracing 2 after bending and stretching both arms against resistance until exhaustion. They appear to have many points of resemblance. The decrease of plethysmogram increases with the amount of pressure exerted. Twenty seconds were necessary to reconnect the tubing after the exercise was stopped.

surrounding tissues. This represents a considerable resistance for the arterial inflow. Furthermore, this dilatation of the venous system presumably causes a vasomotor reflex, resulting in vasoconstriction of the corresponding arteries. Muscular exercise of the upper part of the arm, on the other hand, does not primarily induce venous stasis.

June 30: In the following experiments the influence of exercise alone and in combination with compression of varying strength was investigated in the patient's right arm.

Fig. 10.—Neffy P., June 30, 1928 (experiment B). The tracing shows the changes of the plethysmogram of the right hand after bending and stretching the arm against resistance until exhaustion (E, two minutes ten seconds). Twenty seconds were necessary to reconnect the tubing. After a marked decrease in shape and size the plethysmogram gradually returned to normal after four minutes thirty-four seconds (N).

The blood pressure (brachial artery) was 120 systolic and 90 diastolic. Bending and stretching induced extreme fatigue in the arm after two minutes and ten seconds. The plethysmogram diminished considerably in height and gradually regained normal size and shape in four minutes and thirty-four seconds (fig. 10). In the second experiment, the aircuff was blown up until the manometer indicated 90 mm. of mercury when the arm was stretched. Every time the arm was bent the contraction of the flexor muscles raised the pressure in the aircuff to from 120 to 130 mm. of mercury, causing a repeated temporary, but complete arterial, obstruction in addition to the constant impediment of the venous reflow and the moderate impairment of the arterial inflow. Exhaustion set in after the exercise was carried on for one minute and forty seconds only. The changes in the plethysmogram were similar to those recorded after exercise alone, even the time elapsing before a normal plethysmogram reappeared was practically the same, four minutes and twenty-one seconds. In the third experiment, which was started immediately after the second, the pressure in the aircuff was lowered to 80 mm. of mercury, being 10 mm. below the diastolic blood pressure. Again the contraction of the flexor muscles raised the pressure to 120 mm. of mercury. Exercise

Fig. 11.—Nelly P., June 30, 1928 (experiment D). Pressure equivalent to 80 mm. of mercury was exerted on the upper part of the right arm during this experiment. Bending and stretching of the right arm against resistance was carried on for forty seconds when exhaustion set in. The plethysmogram recorded immediately after reconnecting the tubing presented a straight line until fifty seconds after the exercise was stopped a gradual return to a practically normal plethysmogram began.

was continued for forty seconds only. The tracing obtained after reconnecting the tubing was a straight line at first but after fifty seconds the plethysmogram began to reappear (fig. 11).

The tracings show that exercise of the muscles of the upper part of the arm led more rapidly to a diminution of the plethysmogram after pre-existing stasis. The reappearance of a normal, or at least fairly normal, plethysmogram proves that the flattening observed in this series of experiments was not due solely to the constant stasis—dilation of the venous pathways and the capillaries as well as swelling of the surrounding tissues—but also to a temporary decrease of the arterial blood supply to the hand. A comparison with the experiment in which only pressure was exerted indicates that the diminution of the arterial blood supply of the hand was caused by the exercise.

That exhaustion set in after exercise of a much shorter duration—one minute and forty seconds, and forty seconds respectively—was presumably due to the accumulation of lactic acid, the insufficient blood supply and to the stasis which was even increased since the lowering of the pressure in the aircuff allowed an improvement of the arterial inflow.

July 2, 1928: The patient reported having improved a great deal. Her left arm tired less rapidly after exercise than before. It still became cold and numb, especially when exposed to cold water. This was very marked when she tried to swim. After a few strokes her hand got white, cold, numb and tired, forcing her to give it up, while it took a fairly long while before this condition set in when the patient was just bathing. On examination, the left radial pulse was still weaker than the right. No pulse was felt in the other arteries on the left side. In a series of experiments the reducing influence of exercise of the muscles of the upper part of the arm on the plethysmogram was recorded simultaneously on both sides. Repeated skin temperatures showed that there was very little difference between the two hands at rest, while the delay in the return to normal on the left side after cooling had practically gone. However, even after slight exercise the difference between the left and right hands would reappear.

July 9 and 19: To avoid any possible influence of the touch of the running tap-water, cooling was effected by means of an electric fan placed at the lower end of the bed. The skin temperatures showed that apart from the influence of the position of the fan both cold stimuli had the same effect while the return to normal was practically the same on both sides (fig. 12).

August 7: For the first time a pulse was felt in the left brachial artery, although very faintly. However, the wall of the vessel was easily palpated. The left radial pulse had further increased in strength, though it was still small as compared with the right. The left subclavian pulse was not felt while the carotid was normal. The pulse in the left arm seemed to get larger going peripherally. The blood pressure in the right brachial artery was 132 systolic and 90 diastolic, in the left 100 systolic and 70 diastolic. On the left side, the sounds were muffled and had a duration like a bruit.<sup>8</sup>

August 9: Repeated simultaneous plethysmograms of both hands showed the effect of muscular exercise of the upper part of the arm to be more marked on the left plethysmogram which was much lower than on the right. The left radial pulse disappeared for two minutes after the patient had pulled herself up and down in bed twenty-five times. The pulse rate had gone up from 96 to 108 during this exercise.

August 17: Radial sphygmograms recorded simultaneously on both sides showed the left to miss the characteristic quick rise, the sudden decline and the dichrotia. Muscular exercise of the upper part of the arm resulted in a lowering of the right as well as the left sphygmograms (fig. 13).

As circulatory disturbances had never been noticed in the patient's right arm, it is almost unacceptable that the changes in the sphygmogram on that side were due to the cervical rib. Nevertheless, these experiments were repeated in apparently normal persons, also resulting in diminution of the height of the sphygmogram after exercise.

---

8. Dr. S. A. Levine saw the patient with me.

August 31: The patient reported that she had practically no more complaints, except while bathing and particularly while swimming. The left arm was growing stronger and thicker. She had not returned to work. Examination showed that there was no difference in color or temperature between the left and right hands. The subclavian and the ulnar pulse had not returned, the brachial pulse was just as faint as when it was felt for the first time, while the radial was stronger. Muscular force had definitely increased and exercise could be continued much longer than before.

Comparative examination of four series of skin temperatures showed the considerable influence of the temperature of the surroundings.

Fig. 12.—Nelly P., July 9, 1928. Skin temperatures: the solid line indicates the temperature curve at rest; the broken line, after cooling with an electric fan at the lower end of the bed, and the interrupted line twenty minutes after the cooling was stopped. There was very little difference between the right and the left hand at rest. The delay in the return to normal after cooling had gone, the record showing the same temperature on both sides after twenty minutes. The room temperature was 25.3 C.

In addition to those taken on July 9 and 19, two more series of skin temperatures were recorded on August 25 and 31, the temperature of the room being 25.3 C., 30 C., 26 C. and 28.8 C. on these four days respectively. The series of July 19 and August 31, taken after the patient had been resting in bed for awhile, covered with a blanket, presented practically equal temperature of the hands, while those recorded on July 9 and August 25 showed that the whole left hand, particularly the fingers, were colder than the right. The average tempera-

tures of the finger-tips recorded on the two hot days were 35.8 C. and 34.3 C., while on the two cooler days the corresponding temperatures were found to be 28.9 and 29.9 C. on the right, and 27.2 and 26.3 C. on the left. The return to the original temperature was practically equal in the series recorded on the first three days when cooling was effected either by an electric fan or by tap-water; on the other hand, on the fourth day when the fall of the temperature was caused by exercise the return to normal was delayed on the left as compared with the right (fig. 14).

Two kinds of exercise were performed until the patient became tired: (1) bending and stretching both arms against resistance, (2) pulling herself

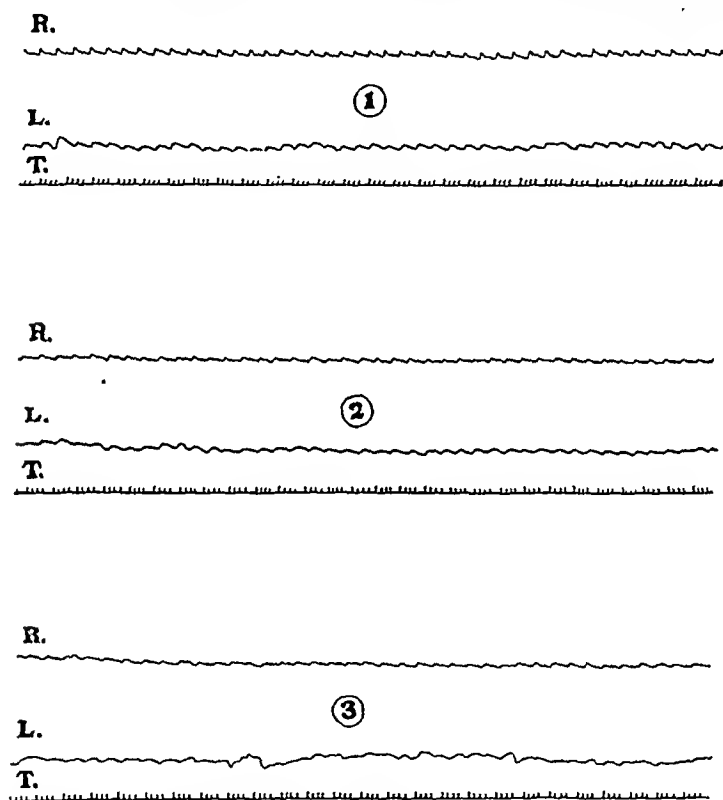

Fig. 13.—Nelly P., Aug. 17, 1928. Simultaneous sphygmograms of the right and left radial arteries: 1, at rest; 2, immediately after bending and stretching both arms against resistance for one minute; 3, after raising and lowering both arms until exhaustion set in. At rest the left sphygmogram was lower than the right and missed the characteristic quick rise, the sudden decline and the dicrotic. Note the diminution of the sphygmograms after exercise.

up and down by means of the iron crossbar above her head. Both resulted in considerable changes of the radial pulse, which became feeble on the right side and disappeared on the left. The left hand was white, cold and dry as compared with the moist right hand. Both radial pulses gradually increased as soon as the exercise was stopped. About two minutes elapsed before they had regained their original character.

this pallor was associated with a decrease in temperature, which soon changed into a rise above the original value, before its return to normal. The skin temperatures of the dorsal side showed considerably smaller variations. In the patient under discussion a few muscular contractions were sufficient to produce these phenomena in the left hand.

#### COMMENT

Although no immediate result was derived from the surgical intervention, it may have been of some help in more readily reestablishing the circulation by relieving the pressure on the artery and by straightening its course. Since the onset and the development of the circulatory disturbances in this case were slow, it seems probable that an operation at an earlier date before the completion of the occlusion might have preserved the circulation through the subclavian artery.

This emphasizes the necessity of operating as soon as circulatory disturbances are noticed.

Surgical treatment is also indicated if the vascular phenomena, which may be elicited by exercise eventually combined with cooling or compression, are more pronounced on the side of the cervical rib. In case of bilateral cervical rib the arm of a normal person may act as a control. In doubtful cases one should resort to plethysmograms, sphygmograms and skin temperatures, as they may give evidence of circulatory disturbances even where the other tests may fail, all the more since they furnish comparable data for future reference. It should be realized that a certain lapse of time (from twenty to forty seconds) necessarily occurs before the reading of the skin temperatures or the recording of the tracings can be started. The temperature of the dorsum of the hand is systematically determined after the volar points have been taken. This represents a difference in time of about four minutes. The only observations which can be obtained immediately after exercise concern the pulse beat and even these refer to a certain period after the exercise is stopped. This must be borne in mind when comparing these records with those made actually during the time that the stimulus is applied, as can be done while compression is exerted.

There is undoubtedly a parallelism between the changes in the skin of the hand during exercise and exposure to cold as well as between the changes in the plethysmogram during compression and after exercise.

Furthermore, the difference between these alterations as observed on the right and on the left side are only quantitative. In normal persons the changes in the skin of the hand occurring during exercise of the arm or hand range within moderate limits. In the patient's left hand all the signs of vasoconstriction were very much exaggerated and of longer duration; the latent period was considerably shortened and the threshold-value of the stimulus was much lower than on the normal side. The considerably lower temperature of the left hand, when cool-

ing was combined with exercise, even as mild as washing or drying her hands, indicated the great influence of exercise.

Although exercise of the muscles of the arm leads to a marked acceleration of the blood flow as well as to an enlarged blood volume in this extremity and in the muscles used,<sup>9</sup> it seems necessary to draw blood away even from the cutaneous and subcutaneous vessels of the hand in order to meet the excessively increased demand of the exercising muscles. That this is more than a mere instance of economical efficiency is proved by the exaggerated alterations in the skin in the patient's left arm. As this increased demand of blood cannot be met with on account of the thrombosis of the subclavian artery and the insufficiency of the other available pathways an unusually large amount of blood is drained away from the superficial vessels, causing extreme pallor, cold, dryness and numbness of the hand. This may at least partly explain the delay in reestablishing the normal color, which moreover, may be attributed to the insufficient blood supply which is inadequate to refill quickly the subsequently dilated capillaries of the skin.

Further evidence for this view is given by the almost equal temperature on both sides after simple cooling. Whatever little difference there is between the right and left sides can be easily explained by transmission of heat from the deeper vessels.

The absence of all pulse distal to the thrombosis is more readily understood than the return of the radial pulse on the tenth day after the operation in the course of which nothing was done to the thrombus itself. As the brachial pulse only came back four months later, the return of the radial pulse cannot be due to canalization or organization of the thrombus, but must be explained by the enlargement of the collateral circulation. The reappearance of the brachial pulse and the return of the blood pressure in this vessel indicate that the circulation had been reestablished in the subclavian artery. However, the lower systolic blood pressure shows that there was still more resistance in the subclavian artery on the left than on the right suggesting a comparatively narrow passage. Further observation will show if this was due to an incomplete organization which may still improve, or to a constant narrowness of the vessel.

The changes in the pulse beat due to the decrease in the pulse pressure and in the pulse rate after the previous increase during exercise can be easily felt at the radial artery. After an excessive and very fast drop, the pulse gradually regains its previous characteristics. The

Hewlett and van Zwaluwenburg: The Rate of Blood Flow in the Arm, *Heart* **1**:87, 1909. Hewlett: *Pathological Physiology of Internal Diseases*, New York, D. Appleton & Company, 1928, p. 24.

plethysmograms and sphygmograms are recorded during the period the pulse is recuperating, thus at a time at which the pulse rate and the systolic blood pressure have already dropped considerably, the latter possibly below the normal rate. At the same time the widening of the capillaries and the relaxation of the local arterioles which allows a local active hyperemia during the exercise is subsiding, resulting in a gradual increase of the resistance of the capillary outflow. The total result is a gradual reelevation of the plethysmogram and of the sphygmogram.

The difference in these curves of the right and left sides can be explained in the following way. The pulse flow may be resolved in two components—the blood flow and the pulse wave. The average rate of the blood flow in an artery depends mainly on the average arterial pressure and the amount of resistance offered by the arterioles and capillaries supplied by the artery under consideration.<sup>10</sup> As the pressure in the arteries of the left forearm and hand must be very low due to the resistance offered by the small caliber of the collaterals, the blood flow is considerably less on the left side. The other factors which determine the blood flow and the pulse wave are practically equal on both sides.

This causes the pulse flow in the left forearm and hand to be very much less than on the right side, resulting in a considerable difference in the plethysmograms and sphygmograms. The resemblance between the plethysmograms of the left hand at rest and during slight compression as well as between those recorded after exercise and during marked compression is due to the fact that the latter likewise causes a decrease of the pulse flow by increasing the resistance in the capillaries and the arterioles.

#### SUMMARY AND CONCLUSIONS

1. A case of bilateral cervical rib presenting gradually increasing circulatory disturbances on one side only is described. At operation, these symptoms were found to be due to an apparently complete thrombosis of the subclavian artery. The return of the radial pulse alone ten days after the operation indicates an increase of the collateral circulation, while the reappearance of the brachial pulse four months after the operation suggests a canalization or an organization of the thrombus.

2. The subclavian artery forms a high and narrow loop in order to pass over the cervical rib. The angle between the scalenus anticus muscle and the cervical rib which normally allows sufficient space for the subclavian artery and the brachial plexus is very much narrowed, especially since the supernumerous rib has a straight instead of a curved shape. This greatly increases the danger of compression since the artery may be imprisoned by dense bands, extensions of the sheath of the

---

10. Hewlett, A. W., and van Zwaluwenburg, J. G.: The Pulse Flow in the Brachial Artery, *Arch. Int. Med.* 12:1 (July) 1913.

scalenus anticus. The high and narrow arterial loop and the sharp angle through which the vessel passes favor the origin and the development of circulatory disturbances which may be caused by repeated traumatism.

3. These circulatory disturbances are due either to arterial compression or to obstruction by thrombosis, generally, however, to both of them since thrombosis is in these cases a sequel of compression. They may be permanent or temporary and change considerably according to the varying demand of arterial blood supply in the extremity.

4. The vascular phenomena presented in the case reported were pallor, coolness and numbness, sometimes also cyanosis of the hand and especially of the fingers. Furthermore, there was a marked tendency to fatigue in the left arm.

5. Skin temperatures, plethysmograms and sphygmograms recorded simultaneously on both sides in various conditions, at rest, during and after exercise of the upper or of the forearm and hand, after cooling alone or combined with exercise, etc., furnish objective evidence of the impaired circulation in the left arm, particularly so during exercise and when there is loss of heat.

6. The division of the scalenus anticus at its insertion as originated by Adson proves to be a simple and efficient procedure to free the artery immediately from pressure. As soon as the vessel is liberated it is seen to slide medially and downward along the declining cervical rib. As this operation only relieves the pressure but does not affect the thrombosis, it is of the greatest importance to operate before the latter has led to a serious degree of obstruction. It, therefore, is necessary to detect the slightest impairment of circulation for the recognition of which the methods described may prove to be useful.

Special care should be taken not to denude the vessel, since the arterial wall may have been severed by the pressure. No arterial branches should be injured as they may form part of the collateral circulation.

7. The same methods may be applied to cases in which intermittent claudication is suspected, since it closely resembles the disorder described in its symptomatology.

# INTRACRANIAL TUMORS IN TISSUE CULTURE\*

FREDERICK E. KREDEL

There are two methods of studying the histologic structure of any tissue. One is by determining the morphology and specific staining affinities of the component cells in fixed sections. This method of attack has brought fruitful results in the classification of the gliomas.<sup>1</sup> The other mode of approach, the direct observation of living cells, has not been used extensively in pathologic investigations, for the securing of cells of most human tissues in a viable condition is a matter of considerable technical difficulty. The methods which are at hand, the technics of supravital staining and of tissue culture, have had only a limited application.

Whether or not these special procedures for the study of living cells will find an increasing sphere of usefulness in laboratories of pathology depends as much on the possibility of their adoption as a routine measure without a prohibitive amount of special training as on a demonstration of their value in the pursuit of specific problems.

In the particular task of the study of the histology of intracranial tumors in this clinic, the tissue culture technic has been found not only readily applicable but also productive of interesting results. A preliminary note<sup>2</sup> has recorded the beginnings of these studies with some observations on the typical cells that grow out of cultures of meningiomas. The present report is a description of the cultural characteristics of a number of intracranial tumors with special reference to the gliomas.

## TECHNIC

Of the various methods for tissue culture, the simple hanging drop technic has been chosen as most suitable for our purposes.

The medium used is heparinized human plasma plus 2 per cent of a dry peptone prepared from Witte's fibrin in Tyrode solution. Carrel and Baker<sup>3</sup> have found that this dry peptone, by virtue of the proteoses which it contains, possesses growth-stimulating properties comparable to those of embryonic juice. The peptone-Tyrode medium is made up in two sections, the sodium bicarbonate being autoclaved separately to avoid the precipitation of calcium and magnesium salts. The two parts are tubed in amounts of 10 cc.; when a tube of each, therefore, is

mixed in a petri dish 20 cc. of solution is obtained of proper osmotic strength and adjusted to  $p_H$  7.2 to 7.4.

A stock of heparinized plasma, prepared by the method of Craciun,<sup>4</sup> is kept on hand for use as needed. A heparin concentration of 1:10,000 will make it possible to keep the plasma for weeks without clotting. The plasma is best obtained from a young subject, for Carrel and Ebeling<sup>5</sup> have reported that growth-inhibiting substances in the blood serum increase progressively with the age of the organism.

The actual technic of preparing cultures by the hanging drop method is too well known to require further description here. The technic followed is essentially that found in the small manual of Strangeways.<sup>6</sup>

The cultures are incubated at 37.5 C. and examined daily in a warm box. Migration of cells from the explant usually begins within the first twenty-four hours but may be delayed until the second or third day. One can keep the cultures alive for weeks by washing them every three days with fresh peptone-Tyrode solution and by making occasional subcultures.

The migrating cells are flattened out on the under surface of the cover slip so that every detail of their structure can be studied under the highest power. The

types of outwandering cells are compared with those observed in the tumor by supravital studies made at the time of culturing.

#### TUMORS CULTURED

The present series of tumors is composed of a variety of types, as shown in table 1. The migration of a sufficient number of tumor cells to make possible an adequate study of their morphology and pattern of growth was used as the criterion for judging cultures satisfactory.

In each case, material from several portions of the tumor is selected for culturing, to increase the chances of securing tissue that is both viable and representative of the tumor.

6. Strangeways, T. S. P.: The Technique of Tissue Culture in Vitro, Cambridge, W. Heffer and Sons, 1924.

It is surprising that, with the simple technic employed, so large a percentage of satisfactory cultures was obtained. Certain types of gliomas have proved particularly favorable material for cultivation. That some tumors grew readily in tissue cultures while others grew to a less extent or not at all was not unexpected. The significance of these differences in growth is discussed below.

*Medulloblastomas.*—There were many reasons to believe that the medulloblastomas would be quite amenable to cultivation.<sup>7</sup> These exceedingly cellular gliomas of the primitive cell type have a rapid clinical course, and the abundance of mitotic figures indicates a rapid rate of multiplication. This expectation has been borne out, for all of three specimens cultured showed excellent migration of cells.

The general form of migrating medulloblasts resembles to a large extent that seen in sections. The cells are small and vary but slightly in size. The shape of the cells is rounded or cuboidal. A short blunt process may give a pyriform outline. The nucleus is rounded or oval and occupies the larger part of the cell. Although no nuclear membrane can be seen, the outline of the clear nucleus is sharp and distinct. A single ill-defined nucleolus can usually be made out. The cytoplasm is scanty and in the living cell is remarkably clear and free from visible granules. A few mitochondria occur, chiefly in the form of short rods. There are no granules nor vacuoles taking neutral red even in old cultures.

These cells grow out from the explant as a gradually enlarging sheet of closely approximated cells (fig. 1). This growth pattern resembles somewhat that of embryonic epithelium. There appears to be no tendency for cells to migrate independently. The cells are evidently fairly soft in consistency. They do not flatten out on the cover slip but remain piled together and overlapping. The shape of each cell, which changes from time to time, as the membrane enlarges, is modified by pressure from contiguous cells.

Noteworthy changes are seen in the migrating cells after several days. The cytoplasm increases in amount parallel with the development of many dark refractile granules. With the exception of a few mitochondria, none of these large cytoplasmic granules shows affinity for either janus green or neutral red. The nuclei become somewhat larger and more vesicular, but remain eccentric in position. The increase of nuclear material is less marked than that of the cytoplasm. Finally,

---

7. It may be stated that the original purpose of this study, undertaken at Dr. Cushing's request, was to learn whether the primitive medulloblast, composing so large a percentage of the fourth ventricle tumors in childhood, was capable of undergoing differentiation on culture into both spongioblasts and neuroblasts. During the few summer months that the author had to give to the work unfortunately only three medulloblastomas were verified.

short cell processes appear, and the resulting cells (fig. 2) become indistinguishable from those seen in cultures of spongioblastoma.

It is possible that some of these changes may be ascribed to degeneration. In other types of cells, however, degeneration granules are stained by neutral red. It is not altogether improbable that these modified cells are an indication of the close histogenetic relation described by

Fig. 1.—A migrating sheet of medulloblasts. Hematoxylin and eosin,  $\times 300$ .

Bailey and Cushing<sup>8</sup> between the medulloblastomas and the spongioblastomas.

On some cultures, a few well differentiated spongioblastic cells (figs. 3 and 4) migrate out even before the appearance of outwandering medulloblasts. In a few cases neuroblasts have been observed. In figure 5,

<sup>8</sup> Bailey, P., and Cushing, H.: Medulloblastoma Cerebelli; Common Type of Mid-Cerebellar Glioma of Childhood, *Arch Neurol & Psychiat.* **14**:192 (Aug.) 1925.

Fig. 4.—A well differentiated cell in a culture of medulloblastoma. Hematoxylin and eosin;  $\times 1200$ .

the cell stained with toluidin blue shows no evidence of the development of Nissl substance.

*Spongioblastoma*.—Cell migration in spongioblastomas is more active than in any other type of glioma cultured. Cells have been observed wandering out from the explanted piece of tissue within six hours after culturing. Large numbers of cells spread out into the plasma clot during the first one or two days. No other cells, with the exception of macrophages, have shown a comparable migratory power.

The outwandering cells vary tremendously in size and shape (figs. 6 and 7). There are many small ameboid cells little larger than a

Fig. 5.—A neuroblast in a culture of medulloblastoma. Toluidin blue;  $\times 1200$ .

medulloblast with all gradations to the huge giant cells with from six to eight nuclei and many cell processes. Bipolar forms with blunt processes are not uncommon. The nuclei show no constancy of size, number or position. They are usually large, oval, and placed somewhat eccentrically. Many nuclei are elongated or even bilobed. Each nucleus contains one or two well defined nucleoli. The cytoplasm is filled with large, highly refractile granules which have an affinity for neither janus green nor neutral red. Mitochondria are more numerous than in medulloblasts.

Particular mention should be made of the giant cells in these cultures. Their nuclei, numbering from two to eight, are usually arranged irregularly. The annular pattern seen in giant cells of the Langhans type is

Fig. 6.—A culture of spongioblastoma, photographed alive and unstained;  $\times 400$ .

Fig. 7—Giant cells in cultures of spongioblastoma, drawn from living culture. Note the variation in the size of the nuclei. Reduced from a magnification of  $\times 1200$ .

occasionally seen but is not characteristic. The mode of formation of these cells has not been studied closely enough to permit a positive statement as to their origin. Such observations as have been made give the impression that they are formed by incomplete division rather than by fusion of cells. As Globus and Strauss<sup>9</sup> have indicated, the variations in the size and disposition of the nuclei in these giant cells may be taken as evidence of atypical cell division.

These giant cells with heavily granular cytoplasm are absolutely pathognomonic of spongioblastoma, for they have been observed in cultures of no other type of gliomas.

*Astrocytoma.*—Cultures of the three specimens of astrocytoma fibrillare in this series showed a small number of migrating cells after several

Fig. 8.—Astrocytes. Hematoxylin and eosin;  $\times 1200$ .

days. The small amount of growth in astrocytomas is in marked contrast to the abundant migration in cultures of medulloblastomas and spongioblastomas. The cells wander out from the explant independently or form a loose reticulum by approximation of cell processes.

The cells are fairly small, multipolar, and may contain many branching processes (fig. 8). The single nucleus is small, oval, and tends to assume a central position. The cytoplasm is finely granular with areas of increased density in the region of the nucleus. The large dark granules of the spongioblastomas are conspicuously absent in this tumor. Occasionally macrophages are obtained in cultures from degenerated portions of the tumor.

9. Globus, J. H., and Strauss, I.: Spongioblastoma Multiforme, Arch. Neurol. & Psychiat. 14:139 (Aug.) 1925.

*Acoustic Neurinoma.*—Although a small amount of migration occurred in five of seven acoustic neurinomas, it was never extensive and occurred only after several days following explantation.

The cells wander out slowly. They tend to remain attached to the explant and to one another in the form of a close network. They are elongated and spindle-shaped. Some are almost acicular. The nuclei are small, oval, and placed either centrally or toward one pole. The cytoplasm is clear with diffuse fine granulations.

As the cells migrate out from the explant they assume a characteristic shape shown in figure 9. The nucleus is situated well forward near the rounded anterior process. There is a long terminal process and several

Fig. 9.—Beginning migration in a culture of acoustic neurinoma, drawn from living culture;  $\times 1200$ .

short lateral ones. A glance at the figure shows the appropriateness of the term "tadpole" cells.

*Meningiomas.*—Large numbers of ameboid cells migrated out in three of four meningiomas cultured. The phagocytic ability of these cells was again demonstrated, as in a previous report,<sup>1</sup> by the facility with which they ingested particulate carmine.

Carrel<sup>10</sup> has found that macrophages and fibroblasts show a differential susceptibility to arsenious oxide. While fibroblasts are killed by

10. Carrel, A.: The Fundamental Properties of the Fibroblast and the Macrophage, II. The Macrophage, *J. Exper. Med.* **44**:285, 1926

a concentration of 1:800,000 arsenic trioxide, macrophages will resist a concentration of 1:200,000. The fact that the outwandering cells in cultures of meningioma remained alive for days in 1:300,000 arsenic trioxide is further evidence that the cells are not of a fibroblastic type.

The cells migrate independently in culture rather than forming the reticular pattern of fibroblasts. There can be little doubt that these migrating cells are at least related to the macrophages. Whether or not they can be shown to be the tumor cells is beyond the scope of the present work.

Macrophages in small numbers have wandered out occasionally in cultures of other types of intracranial tumors, but never in such profuseness as in the meningiomas. The presence of macrophages can be demonstrated in degenerated portions of such tumors as spongioblastoma and astrocytoma, both by supravital technic and in cultures. Their occurrence in these tumors is explained in the basis of their function as scavengers. A few macrophages may migrate out in cultures from

apparently healthy areas of pituitary adenomas and acoustic neurinomas. Their presence in such cases remains to be explained. Carrel and Ebeling<sup>11</sup> have suggested that macrophages may play a nutritional rôle by supplying neoplastic cells with protein split-products necessary for their unlimited proliferation.

#### COMMENT

The observations reported here make possible a differentiation, in the living state, of the typical cells found in three common types of glioma. Table 2 summarizes the more important of the distinguishing features of each type.

A knowledge of these differences in the appearance of the living cells may become of considerable practical importance if examination of tumors in the fresh state (supravital staining and tissue culture) can be developed as a reliable diagnostic procedure. Such an effort is now being made in the Surgical Clinic of the Peter Bent Brigham Hospital with promising results.

11. Carrel, A., and Ebeling, A. H.: The Fundamental Properties of the Fibroblast and the Macrophage: III. The Malignant Fibroblast of Sarcoma 10 of the Crocker Foundation, J. Exper. Med. 48:105, 1928.

It would be interesting to know what relation exists between the growth of gliomas *in vivo* and *in vitro*. The results so far obtained indicate clearly that the two groups of gliomas having the most rapid clinical courses, the medulloblastomas and spongioblastomas, have grown best in tissue culture. The more indolent astrocytomas have grown but slightly and other gliomas not at all. The time since the completion of these studies is too short to make possible at present any exact determination of a relation between the behavior of a tumor in tissue culture and its ultimate clinical outcome in individual cases. If a correlation can be demonstrated, growth *in vitro* might become of some value for prognosis, with due regard for other factors, such as the location of the tumor.

The description of differentiating neuroblasts and spongioblasts in cultures of medulloblastomas confirms the previous report of their presence in fixed sections by Bailey and Cushing.<sup>8</sup> The epithelial pattern of growth of medulloblasts is further evidence for their position in the histogenetic tree as primitive undifferentiated cells capable of giving rise to both nervous and glial elements.

The mode of formation of the giant cells seen in the spongioblastomas deserves further study. It should be possible to observe every detail of their formation by careful studies of cultures of this tumor.

#### CONCLUSIONS AND SUMMARY

1. The method of tissue culture is a practicable means for studying the cellular components of many intracranial tumors. With a simple technique, 62 per cent of a series of thirty-seven such tumors have shown satisfactory growth *in vitro*.

2. There is a characteristic appearance and behavior of the outwandering cells for each type of tumor cultured. These distinctions are sufficiently marked to be used as a basis for diagnosis.

3. There appears to be some correlation between the growth of tumors *in vitro* and the rapidity of their clinical course.

4. Medulloblastomas in culture give rise to cells indistinguishable from cells found in spongioblastomas.

Satisfactory growth in tissue culture has been obtained with a medulloblastoma, spongioblastoma, astrocytoma, meningioma and acoustic neuroma. The characteristics of each type of tumor cultured are described. The significance of the observations reported in the problems of histogenesis and in diagnosis is suggested.

# THE RELATIONSHIP OF THE TOXIN OF *BACILLUS WELCHII* TO THE TOXEMIA OF INTESTINAL OBSTRUCTION \*

ASHLEY W. OUGHTERSON

AND

JOHN H. POWERS

Numerous theories have been suggested to account for the toxemia of intestinal obstruction. Many investigators, among them Murphy and Vincent,<sup>1</sup> Brooks and his co-workers,<sup>2</sup> Dragstedt,<sup>3</sup> Dragstedt and Moorhead<sup>4</sup> and Badile,<sup>5</sup> have submitted evidence for the bacterial origin of the toxin in the contents of the obstructed bowel, but definite proof of the exact nature of the lethal agent has not been established.

The hypothesis was recently advanced by Williams<sup>6</sup> that the toxin of *Bacillus welchii* is the specific agent. This communication focused attention on an organism well known for its ability to produce a powerful exotoxin. Williams presented evidence to support the theory that this anaerobe proliferates rapidly in the stagnant contents of the obstructed small intestine and called attention to the marked similarity between the systemic manifestations of acute intestinal obstruction and of gas gangrene. Experimental and clinical evidence was submitted to support his contention. The intestinal contents from dogs with experimental obstruction and from patients with obstruction and peritonitis were filtered anaerobically and injected into mice, some of which had been protected by *B. welchii* antitoxin. Some of the unprotected mice died; the protected animals all lived. In the clinic, the mortality rates of acute intestinal obstruction and appendicular peritonitis were apparently decreased by the administration of *B. welchii* antitoxin to patients.

6. Williams, B. W.: Importance of Toxemia due to Anaerobic Organisms in Intestinal Obstruction and Peritonitis, Brit. J. Surg. **14**:295, 1926.

Bower and Clark<sup>7</sup> reported favorably on the therapeutic value of antitoxin in a series of twenty-five cases of peritonitis and obstruction. Morton and Stabins<sup>8</sup> likewise submitted evidence to support the contention that *B. welchii* antitoxin possesses specific therapeutic value.

Of interest in connection with Williams' hypothesis was the independent contribution by Scholefield,<sup>9</sup> who demonstrated that the serum of blood withdrawn from the portal radicals of obstructed intestinal loops was lethal for mice.

The purpose of the experiments herein reported was to repeat Williams' work and to demonstrate, if possible, the presence of *B. welchii* toxin in the portal system of dogs with intestinal obstruction. The detection of such toxin in the contents of obstructed intestine was the first essential in the procedure. It was conceivable that the toxin might be present in such minute quantities as to be undetectable by the ordinary laboratory tests. Bull and Pritchett,<sup>10</sup> and Henry<sup>11</sup> showed that *B. welchii* produces both myotoxin and hemotoxin, and that in vitro titration of the hemotoxin affords a relative measure of the myotoxin. The latter is comparatively stable; the former is also stable if kept in sealed containers in the cold but is quickly oxidized when exposed to the air. Small amounts of hemotoxin, when injected into rabbits, stimulate the production of antihemotoxin (Reed and Spence,<sup>12</sup> and Barach and Draper<sup>13</sup>), which can be demonstrated three weeks after injection, reaches its maximum in seven weeks and persists for one year, showing a gradual decrease after from four to seven months.

#### METHODS FOR DETECTING BACILLUS WELCHII TOXIN

The methods for detecting the toxin of *B. welchii* in the contents of obstructed intestine may be enumerated as follows:

1. Inoculation of the suspected material into susceptible protected and non-protected animals. This method was utilized by Williams and should demonstrate the presence of gross amounts of toxin.

7. Bower, J. O., and Clark, J.: *Bacillus Welchii* Antitoxin: Its Therapeutic Value, *Am. J. M. Sc.* **176**:97, 1928.

8. Morton, J. J., and Stabins, S.: *Experimental Studies on the Relation of Bacillus Welchii* Antitoxin to the Toxemia of Intestinal Obstruction, to be published.

10. Bull, C. G., and Pritchett, I. W.: *Toxin and Antitoxin of and Protective Inoculation Against Bacillus Welchii*, *J. Exper. Med.* **26**:119, 1917.

11. Henry, Herbert: *Composition of Bacillus Welchii Toxin*, *J. Path. & Bact.* **26**:497, 1923.

12. Reed, G. B., and Spence, M.: *Duration of Immunity to Bacillus Welchii Toxin (in Rabbits)*, *J. Infect. Dis.* **41**:428, 1927.

13. Barach, A. L., and Draper, G.: *Studies in Experimental Anemia; Immunologic Study of Relation Between Pernicious Anemia and Anemia Due to Welch Bacillus Toxin*, *J. Clin. Investigation* **4**:539, 1927.

2. Injection of the filtrate from the contents of obstructed intestine into rabbits and subsequent titration of the blood serum of these animals for antihemotoxin. Assuming that some toxin might be lost during the process of filtration, the presence of sublethal quantities should be detected by this procedure.

3. Administration of antitoxin to animals with obstruction as a therapeutic measure in combating toxemia. A control series of animals should be treated in a similar manner with normal horse serum. A definite increase in the average length of life of those animals which received *B. welchii* antitoxin should be taken as presumptive evidence that the toxin of this anaerobe is the lethal agent in intestinal obstruction.

4. Clinical evidence of a rapidly developing anemia, and postmortem examination of the animals with obstruction. Severe anemia is a constant observation in all types of infection with *B. welchii*. It is reasonable to assume, therefore, that if the toxemia of intestinal obstruction is due to *B. welchii*, it should be accompanied by anemia. Definite generalized histologic changes are not constant. Hemolytic staining of the endocardium and intima of the great vessels is found most frequently. Fatty infiltration of the heart and liver occasionally occurs.

#### EXPERIMENTS

Intestinal obstruction was produced in dogs by two methods. Closed loops were made and the continuity of the bowel was reestablished by end to end anastomosis. Complete obstruction was created by transecting the terminal ileum and inverting the ends.

Immediately after the death of the animal, the closed loop or whole small intestine was removed, and the semifluid contents were run into large tubes, which were then sealed with a thick layer of petrolatum. These were centrifugated at high speed for about four hours. For aerobic filtration, the supernatant liquid was transferred to a Seitz-Werke bacterial filter. For anaerobic filtration, the fluid was poured into a large buret, which was then sealed. The buret was connected with a Berkefeld candle, and the whole system was rendered air-tight, washed with hydrogen and exhausted three times. Within a few hours, both types of filtration yielded sufficient material for use in the first two groups of the following experiments.

*First Group.*—Gray and white mice were used as test animals. They were separated into two groups. One group was protected by intraperitoneal inoculation with *B. welchii* antitoxin. The unprotected group received normal horse serum. One hour later, each animal of both groups was injected intraperitoneally with equal doses of the filtrate from the contents of obstructed intestine. In a few cases, mixtures of the filtrate and antitoxin, and of the filtrate and horse serum, were incubated for one hour at 37 C. and then injected. The antitoxin was tested repeatedly against a toxin of known virulence, and a quantity sufficient to protect against 2 cc. of the pure toxin was used.

The results of inoculation of intestinal filtrate from eleven dogs with experimental obstruction are shown in table 1. There were no constant lethal effects. In most cases, death was due to spasm and convulsions which occurred within a few hours and did not resemble the lethal effects produced by *B. welchii* toxin.

*Second Group.*—In order to detect the presence of sublethal amounts of toxin in the contents of obstructed intestine, the following procedures were carried out. Each of five rabbits was given not less than 12 cc. of intestinal filtrate, in doses of 3 to 4 cc. administered intravenously. Blood serum was obtained from each rabbit

before injection of the filtrate, and at appropriate intervals thereafter. The serum collected before inoculation was kept in a cold room until the final specimen was drawn.

A known strain of *B. welchii* was grown on meat broth under a heavy seal of petrolatum for eight hours. The broth was then centrifugated at high speed for one hour under a seal of petrolatum and the  $p_H$  was adjusted to 7. The serums obtained from the rabbits both before and after inoculation were mixed with the

\* There were no constant lethal effects.

broth containing the toxin and incubated for one hour in the water-bath. A 5 per cent buffered suspension of fresh normal rabbit cells was added, and the mixture was again incubated for two hours. Thus, the serums of the same rabbit, before and after injection, were titrated simultaneously against the same toxin and fresh normal rabbit cells.

One rabbit (no. 8) was inoculated with a known *B. welchii* toxin, and the blood serum was titrated in a similar manner for control purposes. The results of all the titrations are presented in table 2

There was no increased inhibition of hemolysis in any of the rabbits injected with the filtrate from the contents of obstructed intestine. In other words, the blood serum of these animals did not contain antihemotoxin. One must conclude, therefore, that the filtrate with which they were injected did not contain hemotoxin. The blood serum of the control rabbit, which was inoculated with *B. welchii* toxin,

TABLE 2—Data Pertaining to the Titrations for Antihemotoxin

Rab- bit	Filtrate	Injection		Serum Collected	Inhibition of Hemolysis on "Titration"
		Date	Cc		
1	Injected with filtrate from dog 11	March 16	2	March 16	Normal
		March 17	3	April 16	Not increased
		March 18	3	May 17	Not increased
		March 19	4	June 19	Not increased
2	Injected with filtrate from dog 18	April 20	2	July 7	Not increased

gave complete inhibition of hemolysis when the titrations were performed. A comparison of the titrations of the blood serums of one of the rabbits injected with intestinal filtrate and the serums of the control rabbit injected with *B. welchii* toxin is presented in table 3.

*Third Group*—Therapeutic tests with antitoxin were performed on twelve cats. Obstruction was produced in each animal by transecting the terminal ileum and inverting the ends. Six of the animals were given 5 cc of *B. welchii* antitoxin

intravenously before operation and every other day thereafter until death occurred. Normal horse serum was administered to the remaining six in a similar manner. The results are shown in table 4. The average length of life in each series was the same. Although the number of animals is small, the results suggest that a therapeutic effect was not obtained by the administration of *B. welchii* antitoxin.

TABLE 4.—Result of Therapeutic Tests Performed by Administration of *B. welchii* Antitoxin to Cats with Experimental Obstruction \*

Cats Receiving Antitoxin			Cats Receiving Normal Horse Serum		
Cat	Weight, Kg.	Survived, Days	Cat	Weight, Kg.	Survived, Days
1.....	1.8	2 $\frac{3}{4}$	7.....	2.0	5
2.....	2.1	2 $\frac{3}{4}$	8.....	2.3	5
3.....	2.0	2 $\frac{3}{4}$	9.....	2.4	8 $\frac{1}{2}$

5.....	2.3	5 $\frac{1}{2}$	11.....	2.2	3
6.....	3.6	7	12.....	1.4	5 $\frac{1}{2}$
Average.....	2.5	5 $\frac{1}{2}$	Average.....	2.0	5 $\frac{1}{2}$

\* No beneficial effects were observed.

*Fourth Group.*—Counts of the red blood corpuscles and determinations of the blood and cell volumes were done on several dogs early in the series, but significant changes were not noted, and the studies were discontinued.

Postmortem examinations of all the dogs revealed no hemolytic staining of the endocardium or intima of the great vessels and no pathologic changes which could be directly attributed to the toxin of *Bacillus welchii*.

#### CONCLUSION

The hypothesis that the toxin of *B. welchii* is the lethal agent in the toxemia of intestinal obstruction was not supported by these investigations.

# HORNER AND THE SYNDROME OF PARALYSIS OF THE CERVICAL SYMPATHETIC

J. F. FULTON

In recent years, experimental and clinical neurology have become mutually dependent, and it is refreshing to record an early phase of their association. The theme, too, is a fitting one, since he whom we wish to honor has devoted himself equally to the laboratory and the clinic—to the great benefit of both. The shrewd clinical observations of Horner are, moreover, strongly reminiscent of the "Chief," being painstaking, accurate and far-seeing.

The symptom-complex known variously as the Claude Bernard-Horner syndrome (in France), Budge's phenomenon (among physiologists), but usually and more rightly as Horner's syndrome, is characterized by sinking-in of the eyeball (enophthalmos), narrowing of the palpebral fissure, drooping of the upper lid and slight elevation of the lower, constriction of the pupil, and by certain anomalies in vasomotor and sudorific activity of the neck and face. It is seen in traumatic injuries of the cervical spine, in tumors of the spinal cord and in many other conditions. Recognition of the cause of this clinical picture was largely due to J. F. Horner.<sup>1</sup> The various eponymic designations, however, indicate that others contributed to the discovery.

Johann Friedrich Horner<sup>2</sup> was born on March 27, 1831, at Zurich. His father was a serious-minded physician who was well regarded in the town of Zurich, but owing to a large family, his circumstances were never affluent. Horner's mother was an intelligent, well educated woman who trained all her children in the languages, priding herself, like a true Swiss, on unusual linguistic powers. Johann was also trained in the classics, mathematics and natural history at a primary school in

---

1. He is not to be confused with the well known surgeon of Philadelphia, William Edmonds Horner (1793-1853) who discovered the tensor tarsi muscle of the lacrimal apparatus, *Phila. J. Med. & Phys. Sc.* 8:70, 1824.

2. Biographical material concerning the distinguished Swiss ophthalmologist, though abundant, is little known to English readers. Unfortunately the excellent account of Horner by Horstmann was hidden in a supplement to Hirsch's "*Biographisches Lexikon der Hervorragenden Aertze*," there being only passing notice of him in the main alphabetical list (vol. 3). Horner died in 1886, and in the following year E. Landolt published a full obituary in the *Arch. d'ophth.* (vol. 7, pp. 31-64). The same author also edited Horner's incomplete autobiography ("*Ein Lebensbild Geschrieben von ihm selbst*," ergänzt von Dr. E. Landolt, mit dem Bildnisse Dr. Horners, Frauenfeld, 1887, p. 139). There were also other obituaries: *Deutsche med. Wchnschr.*, 1886, p. 948; in the *Cor.-Bl. f. schweiz. Aertze*, 1887, p. 193; *Klin. Monatsbl. f. Augenh.*, 1887, p. 95. The present account is based chiefly on these sources.

Zurich, and after doing his military service, went to the University of Zurich in 1849, where his previously acquired interest in natural history soon brought him into contact with students preparing for the study of medicine. While in the university he took an active part in the more frivolous features of student life, but at the same time developed a deep interest in science. He entered into political discussions, and on several occasions his freely expressed views brought him before the public eye. On taking up his medical studies at Zurich, he came under the influence of Georg Hermann von Meyer in anatomy, Heinrich Frey in histology, Heinrich Locher-Zwingli (a friend of his father) in surgery, and his clinical work was guided by Karl Ewald Hasse, the well known clinician. But it was to Carl Ludwig that he was most strongly attracted. The great experimental physiologist left the inimitable stamp of his striking personality on every diligent student who came within the sphere of his influence, and Horner proved not the least of those who found themselves at his feet. From him he learned the mechanics of the circulation, the value of experimental methods and also that more intangible breadth of philosophic outlook and imagination so essential for scientific investigation.

In 1854, Horner obtained his doctor's degree from the University of Zurich with the highest honors. His thesis presented at this time dealt with a purely orthopedic problem concerning the curvature of the vertebral column in the sitting position, a subject evidently inspired by H. von Meyer. He then had a "Wanderjahre," during which he visited Munich and Vienna. He attended lectures on a great variety of clinical subjects, but was more attracted to ophthalmology than to the other specialities. It is said that Friedrich von Jaeger, then an old man, showed to his students at Vienna the first volume of the new *Archiv für Ophthalmologie* published by his former pupil, Albrecht von Graefe, and that Horner, on seeing the journal, went to Berlin to study under von Graefe. He arrived in Berlin in October, 1854. Three years previously, Helmholtz, who was then still in Berlin, had published his celebrated description of the ophthalmoscope. Donders was at that time also in Berlin, and (as Landolt has pointed out) never was there a more brilliant conclave of ophthalmologists than Helmholtz, Donders, von Graefe and Horner. Horner was graciously received and soon became warmly attached to von Graefe, their friendship continuing until the latter's death in 1870. From Berlin, Horner went to Paris where he had a highly profitable and stimulating period of study at the eye clinic of Desmarres. While there, he published his first contribution to ophthalmology, which related to the manifestations of constitutional disease detectable by means of the ophthalmoscope (e.g., nephritis).

Though Horner's genius was recognized wherever he went, it was characteristic of him that after a year of travel he chose to return to his native town. For several years he practiced general medicine, and did not specialize in ophthalmology until 1861. In 1856, he had become docent, and in 1862, professor of ophthalmology at the University of Zurich. He continued in active practice until his premature death in 1886. The engraving of Horner which appeared with his autobiography is given in figure 1.

Fig 1—A photograph of the engraving of Horner which appeared as a frontispiece to his "Ein Lebensbild Geschrieben von ihm Selbst, erganst von Dr. Landolt, 1887."

Horner wrote widely in the field of ophthalmology, his papers on keratitis, glaucoma and cataract being especially noteworthy. He also published in Carl H. C. J. Gerhardt's "Lehrbuch der Kinderkrankheiten" (Tubingen, 1880) a section on diseases of the eye in children ("Die Krankheiten des Auges im Kindesalter"). His most important contribution, however, was a brief paper entitled "Ueber eine Form von

Ptosis" in which the syndrome that bears his name was first described. This was published (as were the majority of his other papers) in the *Klinische Monatsblätter für Augenheilkunde* in 1869 (vol. 7, pp. 193-198). As it is brief, it may be translated in full. The first page of the original is reproduced in figure 2.

## Ueber eine Form von Ptosis.

Von

F. Horner.

Wohl manchem meiner Collegen sind Fälle von Ptosis incompleta vorgekommen, die bei erwachsenen Individuen langsam entstanden waren, jeder begleitenden Lähmungserscheinung im Oculomotoriusgebiet entbehrten und die auffallende Erscheinung einer Myosis der gleichseitigen Pupille darboten. Mir war dieses Bild kein neuer Symptomencomplex, als sich mir Ende November vorigen Jahres eine 40jährige Frau mit demselben vorstellte; ja wenige Wochen später sah ich ihn wieder, und abermals bei einer Frau fast gleichen Alters; aber nie war es mir möglich gewesen, für die Auffassung dieser Ptosisform so anregende Beobachtungen zu sammeln, wie in jenem ersterwähnten Fall. Es sei mir erlaubt, hier über diese Kranke Bericht zu erstatten.

Frau Anna Brändli, 40 Jahre alt, eine gesund aussehende Bäuerin mittlerer Grösse, soll schon von Jugend auf oft an Kopfschmerz gelitten haben, der keine Stelle besonders bevorzugte und im Laufe des letzten Jahres eher an Intensität und Häufigkeit abnahm.

Sechs Wochen nach dem letzten Wochenbette, das vor einem Jahre stattfand, bemerkte sie ein allmähliges Herab-

Fig. 2.—The first page of Horner's description of a case of paralysis of the cervical sympathetic (*Monatsbl. f. Augenheilk.* 7:193, 1869).

### ON A FORM OF PTOSIS

BY F. HORNER

Many of my colleagues are familiar with long-standing cases of incomplete ptosis in adults, lacking the usual accompanying signs of oculomotor paralysis but exhibiting the striking symptoms of a myosis of the pupil on the same side. This clinical picture was not new to me when at the end of last November a

woman, 40 years of age, presented herself with these symptoms; less than a week later I saw them again in a woman of about the same age, but it was not possible for me to obtain such crucial information for the elucidation of the ptosis in this case as it was in the first. I may be permitted, therefore, to report here on the first case.

Frau Anna Brändli, aged 40, a healthy-looking peasant woman of medium size, seems to have suffered since adolescence from generalized headache which in the course of recent years had rather diminished in frequency and intensity.

Six weeks after her last confinement, which occurred a year ago, she noticed a slight drooping of her right upper eyelid, which increased very gradually and for about three months had remained constant. The upper lid covers the right cornea to the upper edge of the pupil; the lid is not loose or wrinkled but somewhat sunken into the orbit and is still capable of movement; it is neither injected nor swollen. The upper convex furrows on the right side of the forehead indicate that the frontalis muscle is working as a substitute [for the levator palpebrae superioris].

The pupil of the right eye is considerably more constricted than that of the left, but reacts to light; the globe has sunk inward very slightly and repeated determinations showed that it was somewhat less firm than the left. Both eyes are emmetropic, and have normal visual acuity and early presbyopia.

During the clinical discussion of the case, the right side of her face became red and warm, the color and heat increasing in intensity under our observation, while the left side remained pale and cool. The right side seemed turgid and rounded, the left more sunken and angular; the one perfectly dry, the other moist. The boundary of the redness and warmth was exactly in the midline.

The patient thereupon told us that the right side had never perspired, and that the flushed feeling, and also the ptosis, had only developed in the course of the last year. The redness of the right side of the forehead and cheek was said to be present in the evening as a rule but was also brought on more or less markedly at other times by any emotion.

By feeling the cheeks with the hand, one could perceive a marked difference in temperature. We took steps to establish this precisely and to determine its range. Dr. Julius Michel and Wilh. von Muralt made accurate determinations, some of which I record here. Very sensitive thermometers were read after being warmed in water at about 25 C., and then fastened against the cheek with a cotton compress and adhesive. The temperature was also taken in other localities—behind the ear (over the mastoid process), in the axilla and in the groin.

*I. Temperature of the Cheek.*—EXPERIMENT 1.: Immediately after application, the thermometer on the right recorded 35 C., that on the left, 30 C., the former rising in fifteen minutes to 36.3 C., the latter to 34.1 C. After the temperature on the two sides had become nearly equal and the left cheek had been warmed by the compress so that no difference could be felt with the hand, the thermometers were quickly exchanged, and after five minutes the thermometer on the left rapidly fell to 35.3 C., while that on the right rose to 36.3 C.; after ten minutes the temperatures were equal.

EXPERIMENT 2:

	R.	L.
After 1½ minutes.....	35.0	29.5
After 4 minutes.....	35.8	31.4
After 6 minutes.....	36.1	32.8
After 10 minutes.....	36.1	33.6

After 14	minutes.....	36.2	33.9
After 20	minutes.....	36.4	34.4
After 26	minutes.....	36.6	35.0
After 34	minutes.....	36.7	35.7

## II. Temperature Behind the Ear—

Time	R.	L.	Time	R.	L.
3.36	34.0	30.0	3.46	36.2	35.4
3.38	35.0	32.0	3.48	36.4	35.8
3.40	35.4	33.8	3.50	36.6	36.2
3.42	35.8	34.6	3.52	36.8	36.3
3.44	35.9	35.0	3.56	36.8	36.6

III. *Temperature in the Axilla.*—At first the temperature differed by only three tenths of a degree, and finally (after twenty minutes) by six tenths, the curves being practically parallel, the left lower than the right by a constant interval.

IV. *Temperature in the Groin.*—During the entire period of observation (twenty minutes), the temperature remained the same, 37.6 C. on both sides. The sensation in both cheeks was exactly the same. This investigation thus proves the integrity of the sensory trigeminal nerves, transitory paralysis of the vasomotor fibers in the right trigeminal area; higher initial temperature on the right side with slowly rising (temperature) curve, a low initial temperature on the side with a rapidly rising curve; equalization of both if the observation is continued long enough with the left cheek adequately covered and protected.

Two points necessitate the conclusion that the vasomotor disturbance involves not only the trigeminal area, but also that of the fibers of the cervical sympathetic: first, the slight but distinct variation in temperature in the axillae, secondly, and more important, the small size of the right pupil.

The latter symptom prompted some investigations concerning the action of atropine and calabar. When equal quantities of atropine were instilled into each conjunctival sac the right pupil enlarged slowly and irregularly; after twenty minutes it had not yet reached the size of the left, but remained more constricted and oval, even though more drops were put into the right eye.

When, twenty-four hours after the atropine, equal quantities of calabar were put into the conjunctival sac of each eye, one noticed after ten minutes a marked constriction on the right, and after half an hour almost maximal myosis, while on the left the action of the atropine still continued, and it was only after a half an hour that an insignificant decrease of the effect of the atropine was apparent.

I have already mentioned that the right globe always appeared somewhat softer, but the difference was slight, even if constant. Measurements were made with a Dor tonometer, which is adequate for such comparisons. This difference in tension suggested comparing also the diameter of the retinal vessels. When observed during the stage of elevation of temperature, the veins of the right retina appeared wider and more tortuous than the left, a difference which did not exist when the whole right side was cool, as it was, for example, when the ophthalmoscopic examination was made in the early morning. However, the differences found were so slight that only through repeated examinations by several investigators can the results be securely established.

It is not too much to assert that this experiment with belladonna and calabar speaks for the dual control of the movements of the iris in man; differences in color and caliber of the vessels of the irides have not been found, and therefore it is most probable that we are dealing with right dilator paralysis.

The explanation of the difference in the tension relations of the globe is as yet a matter of personal opinion, since the various functional components of what the anatomist calls the trigeminus cannot yet be accurately distinguished by experimentation.

Let us now turn to the question of the causation of the ptosis. I believe that nobody who had seen all the foregoing symptoms, would be surprised at my considering this ptosis, which comes on gradually but remains incomplete, to be a paralysis of the *musculus palpebrae superioris* supplied by the sympathetic nerve (H. Müller, Harling), and the appearance of the upper lid as part and parcel of the whole symptom-complex. It would thus appear to be the opposite of the condition in exophthalmic goiter in which the upper lid is drawn upward, or better, into the orbit, which by von Graefe and Remak is described as due to the stimulation of the muscle fibers of the lid.

Finally, I may mention that our patient was treated with the constant current, but only for a short period, and therefore without effect.

In many ways, this is a surprising paper, especially in its modest brevity. The minute description of the affected eye, with constricted pupil, soft and sunken globe and dilation of retinal vessels is a model of clarity, and the associated observations of the greater heat and color on the affected side of the face and neck with absence of sweating make his description complete and brilliant. The care which he took to secure accurate determinations of temperature of corresponding points on the two sides of the body is also noteworthy since this was the first time that accurate studies of the temperature of the skin had been made in a clinical case.

An unexpected feature of the paper is its silence concerning related observations in the literature of experimental physiology. Horner was certainly familiar with the experiments of Claude Bernard on cutting of the cervical sympathetic, for these were on every one's lips when he was in Paris, and without a knowledge of them he could not have appreciated the significance of his own observations. In fact, he mentioned Bernard's experiments in other published works. Budge's monograph on the movements of the iris (1855) must also have been familiar to him. Consequently, one may suppose that he assumed his readers were familiar with this experimental evidence. It cannot be denied, however, that Horner's position would have been stronger had he cited more fully the related observations on animals. He also made no mention of the probable cause of the sympathetic paralysis in the case which he described.

Had Horner been more scrupulous in referring to experimental literature concerning the relation of the sympathetic nerve to the eye, he would undoubtedly have mentioned the following observations.

HISTORY OF PHYSIOLOGICAL INVESTIGATIONS ON THE RELATION  
OF THE CERVICAL SYMPATHETIC CHAIN TO THE EYE

The first observations on record are those of the gifted French surgeon, François Pourfour du Petit (1664-1741). In 1727, he published in the *Histoire de l'Académie Royale des Sciences* of Paris a detailed account of experiments in which he severed the vagosympathetic nerve trunk ("nerf intercostal") of dogs (fig. 3). Immediately after the operation, he observed sinking-in of the globe with diminished convexity of the cornea and narrowing of the palpebral fissure, injection of the conjunctiva and relaxation of the nictitating membrane. He also mentioned diminution in the size of the pupil in several experiments, but one is led to believe from his description that this was a subsequent development and not an immediate effect. His observations are indeed remarkable at such an early period, and particularly so, since he was careful to distinguish between the respiratory difficulties due to section of the vagus and the effects on the eye which he believed to be due primarily to paralysis of the sympathetic. It was natural for him to interpret his observations in accordance with the physiology of the time, i.e., in terms of the flow of "animal spirits," believing that the operation prevented their passage from the posterior and anterior parts of the body. Petit's experiments disproved the current belief in the cerebral origin of the cervical sympathetic chain. His paper is also remarkable for the scrupulously careful dissections which he records. For the first time the upper ramifications of the cervical sympathetic chain were traced along the carotid sheath through the sphenoidal sinus to the fifth nerve with which the sympathetic rami are distributed to the eye and face. A translation of the passage in which this remarkable dissection is recorded is given in the legend to figure 4 (in which his original figure is reproduced). One may note incidentally that he found branches passing to the meninges and to the pituitary.

Little was added to the subject until William Cruikshank (1795) repeated Petit's experiments and confirmed them, but he said nothing about pupillary constriction. He emphasized, however, the immediate character of the vasomotor changes. The experiments were again repeated by Dupuy d'Alfort (1816) on the horse, and by Brachet (1837). John Reid (1839), the brilliant physiologist of Edinburgh who died prematurely, studied the problem with great care, and concluded that "the contraction of the pupil, the relaxation of the nictitating membrane, and the partial approximation of the eyelids to each other, take place immediately after injury of the sympathetic and before injury of the conjunctiva presents itself and that they continue after it has disappeared."

Fig. 3.—The first page of Pourfour du Petit's paper describing the results of severing of the cervical sympathetic in dogs (Hist. Acad. roy. d. sc., Paris, 1727, p. 1).

In 1846, Signor Serafino Biffi observed that if the pupil was constricted as a result of section of the sympathetic, dilatation could be induced by galvanic stimulation of the central end of the cut sympathetic nerve. Several years later, Ruete (1847) observed in paralysis of the third nerve that the dilated pupil can be made to dilate still further by the use of belladonna. He accordingly suggested that there were two kinds of motor nerves to the pupil corresponding with the two varieties of muscle fibers known to exist within pupillary muscles, and he inferred that the sympathetic innervated the radial fibers which produced dilatation and that the third nerve supplied the circular fibers which caused the iris to contract. This happy suggestion, which, when first published, was not wholly substantiated experimentally, proved to be the truth.

In 1851, Julius Ludwig Budge<sup>3</sup> and Augustus Waller<sup>4</sup> discovered that the fibers of the sympathetic had their origin in the spinal cord and that they came chiefly from dorsal segments I and II. In sectioning the fibers at their origin or injuring them, the same effects were produced as by section of the nerve in the neck. This was highly significant for it proved for the first time that the sympathetic system took origin in the spinal cord, albeit Petit had provided strong indirect evidence that this was the case. These two writers fixed their attention chiefly on the contraction and dilatation of the pupil, paying less attention to the other phenomena which occurred simultaneously.

The first to make a complete study of all the concomitants ensuant on section and on stimulation of the cervical sympathetic was Claude Bernard. In October and November, 1852, he published two papers in the *Comptes rendus de la Société de biologie*, Paris, in which the complex picture resulting from section of the cervical sympathetic was fully described.

Bernard recognized the following sequelae of sectioning the cervical sympathetic: (1) constriction of the pupil and injection of the conjunctivae, (2) retraction of the eyeball into the orbit and relaxation of the nictitating membrane, (3) narrowing of the palpebral aperture, (4) diminution of intra-ocular tension and progressive diminution in the size of the eyeball, (5) diminution in the size of the nares and (6) increase of temperature over the face on the same side with flushing. With characteristic thoroughness, he then went on to show that all six

3. Julius Ludwig Budge was born on Sept. 6, 1811, and studied at Marburg, Berlin and Würzburg under Buenger and Schlemm. He began to practice in 1834, and spent the greater part of his life at Greiswald where he became widely known for his investigations in anatomy and physiology. His best known work, "Die Bewegung der Iris," published at Braunschweig in 1855, brought him the Monthyon Prize from Paris Academy of Science. It was in this work that he gave a detailed account of his experiments on the innervation of the iris.

4. These were among the earliest of Waller's observations on degeneration in nerve trunks.

of these conditions became reversed if the peripheral end of the cervical sympathetic were stimulated. According to him, the pupil enlarges, the opening of the palpebral fissure becomes greater, the eyeball moves forward in the orbit, the active circulation becomes feeble, and conjunctivae, nares and ears, which were red, become pale. If one stops stimulation, all the phenomena at first seen after section of the sympathetic nerve recur (see also "Leçons sur la physiologie et la pathologie du système nerveux," 1858, volume 2, chapter 15, especially page 499 and the following pages).

In the following year, Budge (1853) published an equally important communication which deserves to be translated in full.

I have found that, in the spinal cord, there is a certain region, extirpation of which augments considerably the warmth of the head. This region is situated between the last cervical vertebra and the third dorsal vertebra, and the phenomenon is transmitted by the eighth cervical nerve and the first two dorsal. Here is an experiment on the rabbit. After having exposed the region of the spinal

Fig. 4.—Petit's figure showing his dissection of the cranial portion of the cervical sympathetic. His description may be translated as follows: "The intercostal nerve [sympathetic], *AA* (fig. 3), enters the cranial cavity with the carotid artery *BB*, piercing first the sheath which envelops the artery within the tortuous bony canal in which it runs. The nerve gives off a number of small branches, *III*, which surround the artery often dividing and reuniting with each other. They arrive together in the sphenoidal fossa; I have omitted the artery in this region in order to show the plexus, *FF*, which the nerve forms by its ramifications in this receptacle. . . . One often sees in the plexus several very small ganglia. Willis and other anatomists have taken this plexus for a small rete mirabile; it is beautifully seen in the dog and in the wolf. It supplies very fine rami to the dura mater and to the pituitary gland and to the carotid artery along which these rami pass; but the largest branches, *EE*, join the anterior trunk of the fifth nerves, *CK*. There are ordinarily two, as one sees in the figure. There is also a third one, *D*, which joins the sixth nerve, *GH*; occasionally one finds only those to the fifth. . . . The nerfs intercostaux thus do not take origin in the fifth nerves." (Hist. Acad. roy. d. sc., Paris, 1727, p. 5 et seq.)

cord just indicated, I sectioned from the last cervical to the third dorsal nerves. In ten minutes the heat of the ear on the same side was noticeably augmented to touch. When cold, the ears of the rabbit ordinarily have a temperature of from 29 to 30 C. or less. On the operated side the thermometer showed from 4 to 5 degrees higher than on the other; the arteries pulsated and the vessels were dilated. It is known that M. Bernard noticed the same phenomenon after having cut the

sympathetic nerve in the neck; and one cannot doubt that it is this nerve through which the influence of the spinal cord is transmitted to the vessels of the head.

The region of the spinal cord just mentioned is the same as where the fibers of the sympathetic take origin which pass to the iris. As I have found that the sympathetic nerve of the iris passes out of the anterior motor root from this region of the spinal cord, I have also observed the same phenomenon relative to heat; for if one cuts only the posterior roots, the heat of the head is not altered, or only slightly so.

After the articles by Bernard and Budge, there were few contributions of great importance, and none prior to the publication of Horner's paper in 1869. The later history of the subject is largely taken up by the elaboration of subtleties, the main facts having already been discovered. Langley,<sup>5</sup> however, made the significant discovery that the preganglionic fibers supplying the dilator pupillae terminate in the superior cervical ganglion where they establish synaptic junction with the postganglionic fibers which pass directly to the pupillary muscles. Langley also studied the levels at which the various types of sympathetic fibers arise: thus, in the cat the fibers which dilate the pupils come predominantly from dorsal segments I and II; the vasomotor supply to the ear and conjunctiva from III and IV, and the pilomotor fibers to the face from V to VI.

One finds in the literature on the cervical sympathetic many controversial papers concerning the existence of a "cilio-spinal center." Budge (1855) had maintained that a center existed in the lower cervical cord responsible for the tonic dilator action of the sympathetic. Braunstein (1894) and others opposed this view, contending rather that reflex dilatation was brought about solely through inhibition of the tonic action of the third nerve. Full discussion of these rather tiresome polemics is given by Anderson (1903).

The trend of more recent work on the central origin of the sympathetic system has been to show that the chief centers lie on the floor of the third ventricle where they pass downward by the posterior longitudinal bundle into the medulla, through the cervical cord and out through the first few dorsal segments. On reaching the pupillary muscles, they have described an almost complete circle. Little wonder that in discussing the subject our "fathers of old" often argued circuitously!

#### HORNER'S PRIORITY

In view of the well controlled experimental analysis of the sympathetic control over the pupil it is surprising that clinical correlations were not made before 1869. Careful search through medical literature has failed to disclose any clinical observations which would rob Horner

---

5. The earlier researches of Langley were well summarized by himself in 1900 in an excellent chapter on the autonomic nervous system in E. A. Schäfer's "Text-Book of Physiology" (see bibliography under Langley).

of his priority. A house surgeon of the Stafford County General Infirmary, bearing the name Edward Selleck Hare, came nearer to the discovery than any one before Horner. In 1838, he described a case of rapidly growing tumor arising on the left side of the neck which gave rise to symptoms of compression of the brachial plexus (numbness and paralysis of the left arm). In describing the case he said, "In addition to the foregoing symptoms, the pupil of the left eye became contracted; and the levator palpebrae ceased to perform its office." The patient became progressively worse, and died ten weeks after the onset of symptoms. At necropsy, a hard irregular carcinoma was found which had involved all the nerves and blood vessels on the left side of the neck. The phrenic and lower cervical ganglions of the sympathetic were also involved. The connection of the tumor with paralysis of the arm is obvious, he said, but the "paralysis of the levator palpebrae which receives a branch from the third pair . . . cannot . . . be referred to any direct communication between the structural disease and these several affections, but rather they must be regarded as an instance of that remote sympathy which is found to exist between distant parts of the same individual and is most frequently displayed in a person of nervous temperament."

Hare<sup>6</sup> thus gives an excellent clinical description and had he been familiar with the experiments of Petit, Cruikshank and others, he would

---

6. Through the courtesy of the Staffordshire General Infirmary, and the manager of *The Staffordshire Advertiser*, the following facts have been secured concerning the career of Edward Selleck Hare (1812-1838). He was born, and passed his youth, at Rough Park near Yoxall in Staffordshire, and from there went to London where he qualified in surgery with exceptionally high honors, at University College. He became appointed House Surgeon at the Staffordshire General Infirmary in January, 1837, and the paper referred to in the text appeared on Sept. 29, 1838. In the same month, however (September, 1838), when but 26 years of age, he contracted a virulent form of typhus fever from a patient whom he was attending, and died on September 28. A notice appeared in *The Staffordshire Advertiser* on September 29, and a full obituary on October 6 (1838), both of which refer to him in terms of more than ordinary praise. "On entering on the discharge of those important duties for which he had so well prepared himself" the obituary reads, "Mr. Hare at once gave proof of the highest qualifications with which the medical philosopher can be endowed. With indefatigable industry, clear views, and a sound and comprehensive judgment, he possessed a zeal and talent for observation which could not have failed to enrich the science to which he had devoted all his energies. Marked from his early youth by intellectual preeminence, and, certain as he was of becoming more and more extensively useful to his fellow-creatures, and of gathering fresh laurels at every future stage of his life, had it been spared, it is painful to reflect that he has fallen, at the early age of 26, a victim to the perils of the profession which, while it honours, enlightens, and protects humanity, but too often requites its ablest and most promising votaries with a premature grave. The last words uttered by this gifted man give proof of his ardor in the cause of science. With his dying breath he

certainly have made the discovery. John Reid (1839), the physiologist, in discussing his own carefully conducted experiments, drew attention to Hare's observations and asked "whether an injury of the cervical portion of the sympathetic in man, such as may possibly occur in certain diseases and operations on the neck, would be followed by contractions of the iris and inflammation of the conjunctiva." He, too, closely approached the discovery, but, like Hare, he was cut off prematurely a year after these observations were made.

Careful perusal of Claude Bernard's works published prior to 1869 (a most stimulating occupation) gives no indication that he observed human beings suffering from paralysis of the cervical sympathetic nerve, nor did he appear to have sought such clinical material. As far as I can ascertain, the same is true of Budge and of other physiologists who had worked in this field. Consequently, since Horner was the first to publish a full description of a case of paralysis of the cervical sympathetic with full recognition of the cause of the patient's symptoms, the syndrome should be associated with his name and with his alone.

#### SUMMARY

A brief account is given of the life of Friedrich J. Horner, the Swiss ophthalmologist—pupil of Ludwig and friend of von Graefe, Helmholtz and Donders—who first described in man the syndrome of paralysis of the cervical sympathetic chain. His original paper has been translated in full and a brief history is given of experimentation on the relation of the cervical sympathetic to the eye. Though Edward S. Hare and John Reid both closely approached the discovery no one really anticipated Horner, and therefore the symptom-complex of myosis, enophthalmos and disturbed vasomotor and sudorific activity of the neck and face should be termed the Horner syndrome.

requested his friends, Dr. Knight and Mr. Hughes, would note any features of his own case that might be recorded for the benefit of his fellow men." This contemporary estimate of Hare, which came to hand after the paper had gone to press, substantiates the belief that, had this brilliant young investigator been spared, he might have anticipated Horner in elucidating the relation of the cervical sympathetic to the eye.

# THE SURGICAL SIGNIFICANCE OF CORONARY OCCLUSION

REPORTS OF TWO CASES \*

COBB PILCHER

Although recognized pathologically for many years and discussed clinically since the Lumleian Lectures of Sir William Osler in 1910,<sup>1</sup> the syndrome accompanying acute coronary occlusion was recognized by very few as a definite clinical entity before the appearance of the now classic paper of Wearn in 1923.<sup>2</sup> Since that time, there have been added to Wearn's nineteen cases some hundred of others, and numerous careful studies of symptoms, physical signs, blood pressure curves, electrocardiographic changes and other observations have been reported. From this extensive literature may be gathered, among others, three significant facts:

1. Coronary occlusion, though variable in its manifestations, is established as a clinical entity and the diagnosis can be made clinically in many cases.

2. Nevertheless, because of the variability of the symptoms and the frequency with which they suggest diseases of other organs, the diagnosis is often extremely difficult, and sometimes impossible, to make.

3. Many of the conditions with which coronary occlusion is most frequently confused are intra-abdominal "surgical conditions"; and several of them, when present, demand immediate surgical intervention.

It seems justifiable to report two highly instructive cases which forcibly illustrate these conclusions.

## REPORT OF CASE

CASE 1.—C. M., a Lithuanian, aged 55, who worked in a restaurant, entered the outdoor department at 6 a. m., April 14, 1928, complaining of severe pain in the upper part of the abdomen. After shoveling about half a ton of coal the night before, he had gone to bed feeling quite well and slept soundly. At 1 a. m. he was awakened by a sudden, prostrating pain in the midpigastrium. He thought he had been shot. The pain was constant, penetrating and had no radiation. The patient was nauseated but did not vomit. He felt as though there were something catching at his throat, but he was not particularly short of breath. His breathing was rapid, but he thought this due to the extreme pain from which he suffered. There were no urinary symptoms. At the end of five hours of continuous pain, he came to the hospital.

His family history and past history revealed nothing of significance. He had never had pain in the chest, palpitation, dyspnea, edema, abdominal pain, nausea, vomiting, diarrhea, excessive constipation, jaundice, or clay-colored, tarry or bloody stools. There had been no genito-urinary symptoms, except a gonorrheal infection thirty-five years before, for which he had been treated and which had never recurred. He denied syphilitic infection by name and symptom.

\* From the Surgical Service of Dr. Harvey Cushing, Peter Bent Brigham Hospital, Boston.

1. Osler, Sir William: Lumleian Lectures, *Lancet* 1:697, 839 and 873, 1910.

2. Wearn, J. T.: Thrombosis of the Coronary Arteries with Infarction of the Heart, *Am. J. M. Sc.* 165:250, 1923.

On examination, he was seen to be in great distress. He lay on his back, his face distorted, grinding his teeth, and groaning with pain. The respirations were shallow and rapid (38 per minute); the temperature was 102.8 F.; the pulse rate, 120. The skin was pale, warm and very moist. There was no cyanosis. The pupils reacted to light. The thorax was of normal shape, and the two sides moved equally with respiration. The percussion note was of normal resonance; no râles were heard. There was no pleural rub. The heart was moderately enlarged to the left, the left border being 12 cm. from the midsternal line. There were no murmurs, shocks, thrills or friction rubs; the sounds were regular and of good quality. The pulses were full, but not bounding or collapsing. The brachial and radial arteries were not tortuous and apparently not sclerosed. The blood pressure was 115 systolic and 80 diastolic. There was boardlike rigidity of the entire abdomen and exquisite tenderness in the epigastrium. No masses or abdominal viscera could be felt. There was no edema of the extremities and the deep reflexes were normal. The leukocyte count was 12,000.

It was believed that the patient had a perforated duodenal ulcer, and he was at once admitted to the hospital. In the ward, the observations were confirmed. He was prepared for operation and given 0.015 Gm. of morphine. Almost immediately, the abdomen relaxed and the respiratory rate dropped to 28. The patient became much more comfortable, but the pulse rate had risen to 140. The blood pressure was 115 systolic and 70 diastolic. This was regarded with suspicion, and the operation was delayed. Occasional weak beats shortly appeared at the wrist and a peculiar systolic "click" was heard at the apex of the heart. Within two hours, these had given way to a definite pulsus alternans and a typical to-and-fro pericardial friction rub. The pulse rate was 160. The blood pressure remained the same. There were a few moist râles at the bases of both lungs.

The patient was transferred to the medical service. His blood pressure there was 105, systolic and 85, diastolic. The pulse rate was 165 and the intensity of the beats irregular. Electrocardiogram showed only a ventricular tachycardia. Tests of the urine, on both services, showed a small amount of albumin, a few hyaline casts and a few white blood cells. The hemoglobin content was 60 per cent, and the red blood cells numbered 4,955,000. No abnormality appeared in the differential leukocyte count. The Wassermann reaction of the blood was negative. Thirty per cent of phthalein was excreted in two hours. Examination of the stool showed no abnormality. Roentgenograms of the chest showed no evidence of pneumonia and no subphrenic gas.

The patient was kept in bed, and the heart rate was kept below 100 with quinidine for the first two days, after which the drug was no longer necessary. There was no pain after the first day. The pericardial rub disappeared on the third day. All electrocardiograms taken after quinidine was discontinued showed normal curves. The systolic blood pressure fell below 100 only once, being reported as 85 (diastolic 60) on the third day. Albumin, casts and cells disappeared from the urine on the fifth day.

Twenty-one days after admission, there was a brief twinge of mild epigastric pain, but no change otherwise. The patient was discharged, after one month in the hospital, with a pulse rate of 70 and a blood pressure of 112 systolic and 62 diastolic. The temperature and leukocyte count were normal.

He returned to the outpatient department at regular intervals. On May 25 (thirteen days after discharge), the heart sounds were normal, the pulse rate was 85 and blood pressure 130 systolic and 90 diastolic. He had done no work, and there were no symptoms. On July 9, he reported that, contrary to advice, he had been lifting light barrels and sawing wood. These exertions and climbing the stairs caused slight precordial pain, which radiated to the epigastrium. The pulse and apical rates were 90 and the blood pressure 175 systolic and 90 diastolic.

On August 9, the patient stated that he had stopped work because of a sensation of pressure in the chest. He had had no pain and only moderate dyspnea on exertion. However, the rate was 165 and the blood pressure was 112 systolic and 80 diastolic. No friction rub was audible, the rhythm was regular, and no murmurs were heard. The electrocardiographic tracing showed a 2 to 1 auricular flutter with an auricular rate of 327.6. The patient was readmitted to the hospital.

The blood pressure on admission was 90 systolic and 60 diastolic. There were a few râles at the base of both lungs, but there was no subjective change, nor could a history of any change be obtained. Five days after admission, after having received large doses of digitalis, the patient's rhythm changed to that of auricular fibrillation, but the following day, sino-auricular rhythm was restored at a rate of 60. There were no symptoms; the blood pressure gradually rose to 124 systolic and 60 diastolic; the pulse rate remained at about 70 after digitalis was discontinued, and the patient was discharged on August 28, nineteen days after admission. During his stay in the hospital, the patient's temperature, which was 100 on admission, quickly dropped to and remained normal, the leukocyte count slowly fell from 14,000 to 7,000. The urine showed no abnormality at any time.

Since discharge, the patient has not worked, and has had no further symptoms. The pulse rate has not been higher than 100 and the blood pressure has risen only to 148 systolic and 78 diastolic. On Nov. 30, 1928, the heart sounds were reported normal.

Two features of particular interest are brought out in this case:

First, there is the narrow margin by which the patient escaped surgical exploration, which would almost certainly have resulted in his death. When he was first seen, it was virtually impossible to make the diagnosis. In retrospection, the only symptoms which should have cast doubt into the minds of the observers were the rapidity of the pulse, and the blood pressure, which was low for a man the age of the patient. Both these observations might well be met with, of course, in a fulminating intra-abdominal infection. The extreme abdominal rigidity and tenderness were difficult to reconcile with any condition outside of the abdomen.

Secondly, the nature of the change which must have occurred before the patient's second admission is still a matter of doubt. Two explanations offer themselves: There was a second coronary obstruction or an extension of the old thrombus to involve new coronary branches; or the small amount of exertion indulged in increased the work of the already damaged myocardium sufficiently to upset its rhythm and lower its functional efficiency. It is probable that both factors played a part, although the absence of pain or friction rub makes it unlikely that there was an acute occlusion.

#### REPORT OF SECOND CASE

CASE 2.—M. C., an Irish housewife, aged 58, was sent to the hospital at 8 p. m., Oct. 9, 1928, by Dr. John Adams, about twenty-four hours after the sudden onset of a severe prostrating epigastric pain. This was sharp and penetrating and persisted without remission until the patient was admitted. There was rather vague transmission of the pain into the substernal and precordial regions and along both costal margins. The patient had been only slightly nauseated and had not

vomited. The bowels had not moved during the previous three days. There had been slight dyspnea, but no palpitation or cough. Deep breathing caused slight exacerbation of the pain.

The past history revealed the following facts of significance: The patient had never had dyspnea, precordial pain, palpitation or edema. For about three years, she had had occasional periods of epigastric distress after meals with eructation of gas. This condition was sometimes relieved by soda, but was, on the whole, rather vague. Six weeks prior to admission, a sudden severe epigastric pain had occurred which had lasted only a few hours, and had disappeared spontaneously. It was not associated with vomiting, jaundice, constipation, diarrhea or palpitation and had no precordial radiation. The patient had never had genito-urinary symptoms. There was nothing of significance in the family history.

On examination, the patient was seen to be an acutely ill, rather emaciated old woman obviously in severe pain. She lay on her back, with knees drawn up, groaning with pain. Her face was distorted and her hands were pressed to the upper part of the abdomen. The skin was wrinkled, lax and warm; there was no cyanosis or jaundice. The pupils were equal and reacted to light. No abnormality was observed in the nose or ears. Only a few lower teeth remained; their condition was poor and their bases were surrounded with pyorrhea alveolaris. The tongue was dry and lightly coated. The neck appeared normal, and there was no glandular enlargement. Expansion of the frail but symmetrical chest was poor. The percussion note was normally resonant throughout, but the bases of the lungs descended poorly. Breath sounds were vesicular. A few dry crackles were heard at the bases of both lungs and there was a faint, inconstant expiratory pleural friction sound low in the left axilla. The heart was not enlarged to percussion; the left border of dulness was 9.5 cm. to the left of the midsternal line and the right border of dulness was not outside the sternal margin. The region of aortic dulness was 6 cm. in width. No shock or thrill could be felt. The heart sounds were loud and snapping. At the apex, there was a short, rough, "clicking" sound which faded into a smooth high pitched systolic murmur at the left border of the sternum. The diastole was clear. The blood pressure was 190 systolic and 130 diastolic. The pulses were equal and regular. The radial and brachial arteries showed moderate sclerosis to palpation. The abdomen showed boardlike rigidity in its upper half and considerable spasm below the umbilicus; there was marked tenderness in the epigastrium and, to a lesser extent, over the whole upper part of the abdomen. No masses were palpated. The liver, spleen and kidneys could not be felt, and there was no evidence of free fluid. The percussion note was tympanitic throughout. There was no edema of the extremities and the reflexes were normal.

The temperature was 100 F., the pulse rate 120 and the respiratory rate 20. The leukocyte count was 7,800; the hemoglobin, 65 per cent. Nothing abnormal was found in the urine. An electrocardiographic tracing showed only a sinus tachycardia and a slight slurring of the S wave in the first lead, with left ventricular preponderance.

The diagnosis was believed to lie between perforated ulcer and coronary occlusion, and, in view of the latter possibility, it was decided to observe the patient for a time. She was given a large dose of morphine which relieved the pain. The pressure, pulse and respirations were observed at half-hourly intervals. During the course of the night, the blood pressure fell slowly, but steadily, the pulse rate rose somewhat and the respiratory rate remained the same. At 7 a. m., the systolic blood pressure was 120 and the pulse rate 135. The spasm was diminished somewhat, and there was no pain. The heart sounds were less loud; the systolic rough sound at the apex was louder and longer, and there was a cor-

responding diastolic "click." During the morning there was no recurrence of pain, the blood pressure and pulse rate remained constant, and the heart sounds grew gradually fainter. The to-and-fro apical sounds, interpreted as a pericardial friction rub, grew less and less intense and by noon could not be heard. At 9 a. m., a second electrocardiogram showed a slight flattening of the T wave and sinus tachycardia. On the basis of the observations, the diagnosis of coronary occlusion was made. The patient was seen by a medical consultant and transferred to the medical service on October 12.

On admission to the medical service, the patient's temperature was 98.8, the pulse rate 105, the respiratory rate 22, the hemoglobin 55 per cent, the erythrocyte count 3,570,000 and the leukocyte count 9,600. The differential count was normal. The urine contained a few white blood cells, but no albumin, red blood cells or casts. The Wassermann reaction of the blood was negative. The blood nonprotein nitrogen was 24 mg. per hundred cubic centimeters, and the phenolsulphonphthalein excretion, 48 per cent in two hours. The heart sounds were not distinct and there was a "loud, blowing, late systolic murmur, heard best over the mitral area and transmitted to the axilla." The blood pressure was 136 systolic and 95 diastolic. A few dry râles were heard at the bases of both lungs, and the abdomen showed only epigastric tenderness to deep pressure.

The patient was kept quiet in bed and given morphine freely. Three days later, she developed signs of fluid at the base of the right lung. Roentgenograms showed a small amount of fluid, signs of early consolidation at the base of the right lung, and a vague gas shadow beneath the right side of the diaphragm. A needle was inserted into the lower portion of the right side of the chest, and 22 cc. of clear yellow fluid was removed. Its specific gravity was 1.016, and it contained 1,400 cells per cubic millimeter, of which 90 per cent were lymphocytes and 10 per cent polymorphonuclear neutrophils.

The roentgen examination was repeated on October 22, thirteen days after admission, on account of the gas shadow previously seen. Films made in the erect position showed increased height of the right side of the diaphragm and a large area of gas with a fluid level as its base beneath the diaphragm. The consolidation at the base of the right lung had cleared considerably. A definite diagnosis of subphrenic abscess was made by Dr. Sosman of the x-ray department. The patient was retransferred to the surgical service on October 23.

During the patient's stay in the medical service, her temperature had slowly risen to 102 F.; the pulse rate had been maintained at about 140, the leukocyte count had risen gradually to 21,000 and prostration and emaciation had steadily increased. Electrocardiograms repeatedly showed a normal condition.

When the patient reached the surgical ward, she was prepared at once for operation. An incision was made over the ninth rib posterolaterally. A portion of the rib was resected and the diaphragm sutured to pleura around the margin of an oval area about 6 by 4 cm., through which it was proposed to drain the abscess at a second stage in about forty-eight hours. The procedure was carried out under local anesthesia, and no apparent change occurred in the patient's condition.

The following evening, after having rested quietly since the operation, the patient suddenly began to cough up huge quantities of foul, greenish-yellow pus with the odor characteristic of infection by *Bacillus coli*. Postural drainage was inaugurated, and approximately 1,500 cc. of pus was evacuated within an hour. In spite of the free evacuation, however, signs of the filling up of both lungs shortly appeared, the temperature began to rise, respirations became rapid and shallow, a rapidly increasing cyanosis appeared, the pulse rate rose swiftly and, four hours after the first cough, the patient died an obviously respiratory death.

Unfortunately, permission could not be obtained for a postmortem examination.

This again is a case difficult or impossible to interpret definitely even after weeks of observation with every available facility for study. It is probable that there was an ulcer which perforated into the lesser omental sac and formed a subphrenic abscess, and that the latter subsequently ruptured the diaphragm into a large bronchus. But this must deny the existence of, or fail to explain satisfactorily, the pericardial friction rub. A possible explanation is that the latter was a pleuro-pericardial rub caused by increased excursion of the heart, and its brief duration offers some support of this theory. It has been suggested that, following the formation of a cardiac infarct, there occurred the following series of events: the formation of mural thrombi in the right ventricle, at the site of infarction; secondary pulmonary infarction at the base of the right lung with the subsequent formation of a pulmonary abscess which perforated the diaphragm, and terminal rupture of the abscess into a bronchus. This seems unlikely in view of the roentgen observations and of the definite odor of the pus.

#### COMMENT

A great deal of light has been thrown on the causation of "coronary" pains by the recent revolutionary paper of Keefer and Resnik.<sup>3</sup> The pathology of the condition, with its resultant physiologic changes, is fairly well understood. The frequency of its occurrence, however, and the difficulty with which it is diagnosed are not generally realized, perhaps least of all by surgeons, to whom these facts are of so much concern. Numerous writers, including Benson,<sup>4</sup> White,<sup>5</sup> Hardt,<sup>6</sup> Gardinier<sup>7</sup> and Coffen and Rush,<sup>8</sup> have pointed out the similarity of this condition to acute intra-abdominal conditions, especially gallstone colic and perforated ulcer, but it is surprising how few such papers have emanated from surgical clinics.

The two cases here reported admirably illustrate a difficulty often encountered, as well as the great importance of keeping in mind the possibility of coronary occlusion in cases of acute pain of the upper portion of the abdomen, and of exhausting every effort to make a correct diagnosis.

## LUDWIG'S ANGINA\*

ASTLEY P. C. ASHHURST, M.D.

PHILADELPHIA

Medical men have always been, and I suppose will always be, divided into two groups: first, the Hippocratic group, composed of those who, like Hippocrates, object to the unnecessary multiplication of diseases and who prefer to assign so-called new diseases to their proper places under already recognized pathologic processes; and, second, the Cnidians, for whom every new symptom and every complication constitutes a new disease. But though my own inclinations lean toward the former school, it is impossible to deny that new clinical entities are from time to time recognized by acute observers, and that in this way both the science and the art of medicine are advanced. Consider, for instance, appendicitis: Is it, or is it not, a distinct disease? The Hippocratic group will argue that it is not a new disease but merely an ordinary disease which is known as inflammation; and so far they will be correct. But its location gives it symptoms and predisposes it to complications which an ordinary inflammation occurring in other situations does not possess. Hence it is correct, in clinical work, to recognize appendicitis as a distinct disease. No doubt appendicitis had always existed in the human race, just as Ludwig's angina had always existed;<sup>1</sup> but it was not recognized until comparatively recent times.

### HISTORICAL

In 1836, Dr. Ludwig,<sup>2</sup> Vicedirektor und Leibarzt in Stuttgart, contributed to his local medical journal an article entitled "Ueber eine . . . Form von Halsentzündung" (Concerning a Variety of Neck Inflammation). He had observed five patients with similar symptoms: three of these patients died, while two recovered under medical treatment and local applications.<sup>3</sup> In subsequent numbers of the same

\* Submitted for publication, Jan. 19, 1929.

\* Read by invitation before the Western Surgical Association, Dec. 14, 1928.

1. Parker (*Lancet* 2:570, 1879) and, more recently, Muckleston (*Tr. Am. Laryngol. Rhin. & Otol. Soc.* 33:42, 1927) gave various references to descriptions of what were probably similar cases antedating Ludwig. Vachey and Dechaume (*Lyon chir.* 24:642, 1927) quoted the description of this lesion given by Gensoul in 1830.

2. Ludwig: *Med. Cor.-Bl. d. Württemb. ärztl. Vereins, Stuttgart* 6:21, 1836.

3. As Roser (*Deutsche med. Wchnschr.* 9:153, 1883) pointed out, at the date Ludwig published his description, no one opened deep abscesses with a knife. Dupuytren, Velpeau, Delpech and Roux, the authoritative surgeons of the time, ordered "blistering plasters" for phlegmons.

journal, other German physicians reported cases which they thought similar to those described by Ludwig, though some of them do not seem to me to correspond with sufficient accuracy to be acceptable.

This Stuttgart journal did not have a wide circulation,<sup>4</sup> but Ludwig's paper and the subsequent case reports were noticed at considerable length in an editorial in the *Gazette médicale de Paris* and in Schmidt's "Jahrbücher" for 1837;<sup>5</sup> it was from the latter sources and not from the original that a knowledge of the condition gradually spread.

In his original contribution, Ludwig insisted that the condition (1) was an inflammation of the cellular tissues, (2) began around the sub-maxillary salivary gland, and (3) subsequently invaded the neck and the floor of the mouth, and (4) that it ran a course which grew progressively worse, with death in ten or twelve days or gradual recovery. Autopsy showed a phlegmonous process in the regions indicated and gas in the abscesses. Ludwig thought that the disease he described might better be called an inflammatory hardening of the cellular tissue of the neck, "brandigter Zellgewebsverhärtung des Halses." It was characterized, he noted, by (1) the insignificant inflammation of the throat itself, which, even if present early in the disease, faded away soon; (2) the peculiar wooden hardness of the cellular tissue, on which an impression cannot be made (i.e., it was not like an ordinary edema); (3) the hard swelling under the tongue and the callous swelling on the inner border of the mandible; (4) the well defined border of this hard edema in the neck, and (5) the absence of disease of the "glands" (Drusen), although their surrounding cellular tissue was affected.

"Cellular tissue" was the term still used in the early part of the nineteenth century for all tissues provided with interstitial meshes—subcutaneous, submucous, subarachnoid, etc.; and it is still in use at the present day for the subcutaneous and retroperitoneal tissues, though the term areolar tissue is preferred by some. Of course the term "cellular" does not imply that "cells" are present in the sense in which cells have been understood since the days of Schwann, but that cell-like, honeycomb-like spaces are present (Stricker).<sup>5a</sup> Cellulitis is the term still in common use in English speaking countries for inflammation of this tissue, and though the French prefer the terms phlegmon, phlegmoneux, they sometimes use the word cellulite; while the Germans say Zellgewebsentzündung, inflammation of the cellular tissues.

Surgeons have, as usual, separated into two camps concerning the individuality of this disease. There are those like Nélaton,<sup>4</sup> who are

4. Nélaton (Bull. et mém. Soc. de chir. de Paris 18:489, 1892; Gaz. d. hôp. 65:757, 1892) said that he could not find Ludwig's original article in Paris.

5. Ludwig: Gaz. méd. de Paris 4:577, 1836; Schmidt's Jahrbücher, Leipzig, 1837, vol. 15, p. 25.

5a. International Encyclopedia of Surgery (Ashhurst) ed. 2, New York, 1888, vol. 1, p. 41.

Hippocratic in their tendencies and deny that Ludwig's angina is a specific disease; they claim that it is merely an ordinary cellulitis, similar to that which affects the limbs. Nélaton said that the term Ludwig's angina "did not correspond to any well defined malady, and did not merit being preserved." This probably was the view of the following writers, in whose textbooks or systems of surgery I have been unable to find any account of such a condition as Ludwig described; much less is it mentioned by his name: Dupuytren (1839), A. Nélaton (1844), Gibson (1845), Chassaignac (1859), Erichsen (1869), Holmes (1869), Gross (1872), Ashhurst (1872 and 1881),<sup>6</sup> Agnew (1878) and Bryant (1879). Though König<sup>7</sup> discussed Ludwig's angina under this name, but without mentioning a sublingual lesion, he was averse to considering it a special disease; he believed it to be a submaxillary abscess of extremely dangerous variety, its only special characteristic being that it occurred in epidemic form. Semon<sup>8</sup> (1895) also denied the specificity of Ludwig's angina. Boehler,<sup>9</sup> whose Paris thesis (1885) is much quoted, also was Hippocratic in his tendencies: the case reports he collected from 1836 to 1850 were mostly from German sources; there is a gap, then, until 1875, when French and English reports appear. Boehler said that because Ludwig's angina is always secondary to a focus in the mouth, it is not a specific disease. In this sense he is certainly correct.

In the lengthy discussion of the subject before the Surgical Society of Paris (1892), precipitated by Nélaton's remarks in reporting, in 1892, on a communication presented by Linon, Delorme<sup>10</sup> took the opposite view, recognizing the condition described by Ludwig as a clinical entity, though preferring the term sublingual phlegmon to that of Ludwig's<sup>11</sup> angina. It is only since the important discussion of the subject by the French surgeons in 1892 and especially in this country since the discussions in Philadelphia aroused by the reports of Davis<sup>12</sup> (1906), Thomas<sup>13</sup> (1908) and Price<sup>14</sup> (1908), that Ludwig's angina has received general recognition; now every textbook and system of surgery describes it more or less accurately and completely.

13. Thomas, T. T.: Ann. Surg. 47:161, 1908.

14. Price: Am. Surg. 48:649, 1908.

I myself have defined it as follows: "It is an acute inflammatory process involving the cellular tissues of the floor of the mouth and the submaxillary region of one or both sides of the neck." It is important to note that in this definition the main clinical features of the disease are indicated. It affects the connective tissue spaces, being a cellulitis, not a lymphangitis or lymphadenitis; the lymph nodes and the submaxillary and sublingual salivary glands are not primarily diseased but may be invaded secondarily. It involves both the sublingual and the cervical tissues; it is not confined to either. It may begin in either situation but until it spreads from the submaxillary tissues to the sublingual tissues or, in the reverse direction, from the sublingual tissues to the submaxillary region, it does not constitute Ludwig's angina. As long as it is confined solely to the submaxillary and cervical tissues, it is merely a submaxillary or a cervical cellulitis (case 19); as long as it is confined to the sublingual tissues, it is merely a sublingual cellulitis (case 22). It is the simultaneous involvement of the submaxillary and the sublingual tissues in a confluent septic cellulitis that warrants the condition being recognized as a distinct clinical entity. If physicians refuse to give it such recognition, they are making a backward step comparable to that which would be taken if they still refused to recognize the clinical entity appendicitis as distinct from typhlitis or enteritis or peritonitis.

Some who have studied Ludwig's angina have contended that it is a lymphangitis and a lymphadenitis, not a cellulitis. Such was the view of Thaden<sup>15</sup> (1872), of Tillaux<sup>16</sup> (1877), of Poulsen<sup>17</sup> (1893) and of Thomas (footnote 13)<sup>18</sup>

Hamann<sup>19</sup> (1899) followed Roser<sup>20</sup> (1883) in believing that Ludwig's angina was due to inflammation spreading along the ducts of

15 Thaden, in Boehler (footnote 9).

16 Tillaux. *Traité d'anatomie topographique*, Paris, 1877, p 438

17. Poulsen. *Deutsche Ztschr f Chr* 37:55, 1893

18 It is interesting to note that in the first and second series of the Index Catalogue of the Surgeon General's Office, U S Army, the heading Ludwig's angina refers the reader merely to Neck, Abscess of, while in the third series, publication of which commenced with the year 1918, the reference is to Throat, Inflammation of, Septic. This indicates a correct tendency to separate cases of Ludwig's angina from the general group of abscesses of the neck and to recognize the disease rather as a phlegmonous process (cellulitis). Thomas later (in Keen's Surgery, Philadelphia, 1913, vol 6, p 418) spoke of Ludwig's angina as a cellulitis but stated that the infection passed from the mouth "to the submaxillary lymph nodes, where it takes on virulent activity, leading to a rapidly spreading periadenitis. After the development of an extensive cellulitis here, or occurring simultaneously with it, the process extends to the floor of the mouth." In this explanation Muckleston follows Thomas, who himself follows Tillaux (footnote 14), who thought cellulitis always secondary to lymphadenitis, the latter itself being due to dental infection.

19 Hamann. *Cleveland M J*. 4:387, 1899

20 Roser. *Deutsche med Wchnschr* 9:153, 1883

the submaxillary and sublingual salivary glands. This view, however, which never was held by many students of the subject, is now generally abandoned.

#### CELLULITIS AND LYMPHANGITIS OR LYMPHADENITIS

On account of this apparent confusion of mind in regard to the pathogenesis of the disease, it is, perhaps, worth while to inquire just what cellulitis is and in what ways it differs from lymphangitis and lymphadenitis. A familiarity with these fundamental questions is often taken for granted; but actually our knowledge of them is not extensive.

In the first place it may be said that modern histologists appear to be fairly well agreed that the lymphatic system is a closed system, not having any communications with the cellular tissues. I believe that all those whose views are worthy of consideration have now acknowledged the correctness of Sappey's original statement<sup>21</sup> (1886) to the effect that the lymphatic system is entirely separate from the connective tissue spaces. Sappey asserted that the lymphatic capillaries arise in tiny closed vessels on the surface of the skin and mucosa, and that the further one gets from either of these surfaces, the scarcer the lymphatic channels become; that beneath the superficial layers of the skin or the mucosa there exist neither "capillicules" (minute capillaries) nor "lacunes" (areas in which several capillicules join each other); that in the deep layers of the skin and mucosa such channels do not exist, nor are found in the subcutaneous or in the submucous cellular tissues, in which only lymph vessels (not capillaries) exist. Sappey asserted that there are no more lymphatic vessels passing through the subcutaneous tissue in fat people than in thin people.

If these facts as to distribution of lymph capillaries and lymph vessels are true (and, in the main, Sappey's conclusions are accepted by modern authorities), they explain largely the difference in the clinical features between lymphangitis and cellulitis. The former may exist, perhaps, in connection with the mucous membranes (though next to nothing is known of it in such situations), but it is in the skin, especially the skin of the limbs, that it is most familiar; it arises from lesions of the skin itself, not from lesions of the deeper structures; it is not as a rule attended by much swelling; there is little if any evidence of cellulitis, and the lymph nodes are habitually involved (often, indeed, without any visible involvement of the lymphatic vessels in the limb itself). Cellulitis, on the contrary, seldom or never develops as a complication of superficial skin lesions, but is almost always due to septic wounds which penetrate beneath the skin or at least as far as its deeper layers; it is attended by much swelling, but not by lymphangitis; the skin itself is

21. Sappey: *Déscription et iconographie des vaisseaux lymphatiques*, Paris, 1886, p. 6.

not reddened until quite late in the disease, or until suppuration impends, and it seldom gives rise to lymphadenitis. But it may be asked at this stage, What is erysipelas? I class erysipelas as a septic dermatitis; in a sense, it is a cellulitis of the skin:<sup>22</sup> It is neither a lymphangitis, nor yet is it a cellulitis in the accepted sense of the term, and yet it partakes of the nature of both: it is red like lymphangitis; like it also, it involves the skin, and in typical form it never suppurates, though bullæ frequently form; but it is seldom attended by lymphadenitis, yet it is accompanied by much swelling, and in these two respects it resembles cellulitis. Is it that different varieties of the streptococcus are mainly responsible for these differences between lymphangitis, cellulitis and erysipelas; or is it chiefly a matter of the structures which they invade? These are theoretical questions which any fool can ask, but which many wise men are unable to answer.<sup>23</sup> Yet every once in a while a patient is encountered who appears to have both erysipelas and suppurative cellulitis at the same time, in the same limb; and physicians satisfy their consciences by naming the disease phlegmonous erysipelas.<sup>24</sup>

Lymphadenitis in the cervical or submaxillary regions arises, as elsewhere in the body, from surface lesions, i. e., lesions of the tonsils, the mucous surfaces of the cheeks, mouth, tongue and nose; of the air sinuses, the fauces, the nasopharynx, oropharynx and larynx, and from surface lesions of the face and scalp. These are not the lesions which cause cervical, submaxillary or sublingual cellulitis. The causes of cellulitis here, as elsewhere, are infections arising in the cellular tissue itself, which are propagated by continuity but not through lymphatic channels. Infections arising in the teeth and their sockets are among the commonest causes of cellulitis; and it is a gross mistake, as pointed out by Sébilleau<sup>25</sup> (1921), to consider cervical abscesses of such origin as instances of suppurative cervical lymphadenitis. As a matter of fact they are, with few if any exceptions, examples of suppurative cellulitis. This is shown, as stated by Sébilleau, by the following facts: (1) After extraction of the diseased tooth, pressure on the submaxillary swelling will cause pus to be discharged from the socket of the tooth, and in

22. In a somewhat similar sense, acute septic osteomyelitis is a cellulitis of the bone marrow.

23. Panton and Adams (Lancet 2:1065, 1909), attempting to find answers to such questions, concluded that "there is direct evidence that the same organism may produce at one time erysipelas and at the other cellulitis." The difference depends, they said, on the site of inoculation: if it is the epidermis, erysipelas results; if it is the subcutaneous tissues, cellulitis results. They found that *Staphylococcus aureus* was the cause of lymphangitis, a lesion which never gave a growth of streptococcus in their experience. One of their interesting *obiter dicta* is to the effect that lobar pneumonia is a disease process similar to erysipelas or cellulitis, differing only in its situation.

24. Such, perhaps, was the condition in case 17, recorded here.

25. Sébilleau: Presse méd. 29:213, 1921.

many cases the cervical abscess may be emptied in this way or after careful probing through the socket of the tooth or alongside the alveolus; such evacuation, as Ivy<sup>26</sup> said, could not possibly occur through inflamed lymph channels; (2) after the submaxillary swelling is opened (as is required in all patients not seen before the overlying skin becomes affected), probing detects bare bone at the bottom of the cavity; (3) the existence of trismus, always present when the molar teeth are the focus, indicates that the mandible is fused with the inflammatory mass in the neck; such fusion does not occur in cases of lymphadenitis, nor is the latter condition usually accompanied by trismus.

## PATHOGENESIS OF LUDWIG'S ANGINA

It remains to explain in what manner cellulitis occurs both in the sublingual tissues and in the submaxillary tissues at the same time. It is to be well understood that Ludwig's angina begins either in one site or the other, but is not to be considered fully developed until both sites are involved.

Of twenty-seven cases listed as Ludwig's angina in the records of the Episcopal Hospital, Philadelphia, since 1905, I have rejected nine as not being properly diagnosed. These were cases of the following conditions: (1) quinsy, 1906; recovery; (2) stomatitis, 1912; recovery; (3) cellulitis of the neck from perforation of the larynx, 1915; death; (4) sublingual cellulitis, 1916; recovery (case 21); (5) suppurative cervical adenitis, 1916; death; (6) Vincent's angina, 1918; recovery; (7) stomatitis and parotitis, 1918; recovery; (8) submental cellulitis, 1920; recovery; (9) submaxillary cellulitis, 1925, recovery. This leaves eighteen cases which are properly classed as Ludwig's angina. I myself have observed about twelve of these patients, though only five of them were admitted to my service. These eighteen cases are summarized in the accompanying table:

*Cases of Ludwig's Angina from the Episcopal Hospital*

	Date	Name	Sex	Age	Chief	Cause	Result
1	11/11/05	Samuel Biggin.....	M	61	Frazier	Dental	Recovery
2	4/21/08	Thos. Chamberlain.....	M	29	Neilson	Dental	Recovery

\* Died seven weeks later from senility.

26. Ivy, R. H., in Nelson's Loose-Leaf Living Surgery, New York, Thomas Nelson and Sons, 1928, vol. 2, p. 643.

It will be observed that in eleven of these eighteen cases the history is definite and positive in stating that dental infection was the cause of the disease. Three patients (those in cases 11, 12 and 15) were so ill on admission that a clear history could not be obtained; these patients died. In an infant, aged 11 months (case 7), no cause was recognized. This leaves only three patients (those in cases 13, 14 and 17) in whom the absence of dental infection can be assumed.

Since dental infection (with or without trauma from extraction of diseased teeth) is one of the most frequent causes of Ludwig's angina, it is well to have clearly in mind the pathologic lesions present and the influence exerted on the spread of the infection by the surrounding anatomic structures. I have not found a more succinct account any-

Fig. 1.—Alveolar abscess pointing over body of mandible, four days after extraction of tooth. Uneventful recovery. (From the Episcopal Hospital.)

where than that given by Moty,<sup>27</sup> as long ago as 1892, in the discussions already mentioned at meetings of the Society of Surgery of Paris:

1. Caries may cause gangrene of the dental pulp, the infection spreading from there to the apex of the tooth and then to the alveolus, there causing fungosities with absorption of the cement of the tooth and of the corresponding wall of the alveolus. The pus discharges first by the canal inside the tooth, but if the canal is obstructed or is insufficient in size, a phlegmon develops.

2. Usually, Moty pointed out, the pus pierces the alveolus in its thinnest part, on the outer surface of the mandible, and forms a dento-alveolar abscess in the surrounding cellular tissue (fig. 1). The pus seldom works its way between the alveolus and the neck of the tooth because the latter is united to the gingival mucosa by resistant fascia; so it points toward the skin, or toward places in the buccal mucosa more or less distant from the diseased tooth.

27. Moty: *Bull. et mém. Soc. de chir. de Paris* 18:536, 1892.

3. But, Moty said, when the process is acute (as after illtimed filling of a tooth), there is no time for absorption of the alveolus to occur; so the infection enters the dental canal of the mandible, spreads toward the spine of Spix and makes its way toward the cellular tissue which separates the upper surface of the mylohyoid from the gum, or toward that which surrounds the carotid vessels in the neck. The strangulation resulting from inflammation of the dental canal may cause osteomyelitis of the mandible

4 If a back tooth or a wisdom tooth is infected in this way, the outer wall of the mandible is so thick that perforation occurs only on the inner wall, so that the sublingual tissues are infected at once.

Fig. 2.—Drawing from a dissection by the author to show the fascia colli: On the right of the picture the skin (*D*) only has been reflected, exposing the platysma; on the left of the picture (the subject's right), the platysma also has been turned down exposing the fascia colli, through the fibers of which can be seen indistinctly the parotid (*A*), the submaxillary salivary gland (*B*), the anterior belly of the digastric (*C*) and the hyoid bone. Figures 2, 3, 4, 5, 6, 7 and 8 are from dissections made by the author in the Laboratory of Operative Surgery, Medical School of the University of Pennsylvania

It is evident, from a study of figures 2, 3, 4, 5 and 6 that the fascia surrounding the submaxillary salivary gland and the attachments of the mylohyoid muscle have an important effect in the spread of these infec-

tions. Figure 2 shows the fascia colli exposed by reflection of the platysma from the body of the mandible. This fascia covers the superficial surface (that toward the skin) of the submaxillary salivary gland, and splits to envelop the sternomastoid and to surround the digastric muscle. This muscle (the digastric) forms a shelf on which the submaxillary salivary gland rests.

The fascia colli also sends a partition inward between the submaxillary salivary gland and the parotid, thus completing the capsule for the

Fig. 3.—Section through floor of mouth, back of symphysis, fixed in solution of formaldehyde. A, sublingual salivary gland.

former. This capsule is pierced below (and median to the digastric muscle) by the entrance of the facial (external maxillary) artery and above, near the body of the mandible, for the exit of this artery, which traverses the submaxillary space;<sup>28</sup> the fascia is also pierced below by the lingual artery, which finally leaves the submaxillary region and

28. The facial vein on the contrary, does not traverse the submaxillary space, but runs in the layers of that portion of the fascia colli which separates this space from the platysma (see fig. 4).

enters the cleft between the hyoglossus muscle and the intrinsic muscles of the tongue. In this region (toward the floor of the mouth) the submaxillary capsule is deficient, since the submaxillary salivary gland here curls around the posterior border of the mylohyoid muscle, to become practically continuous with the sublingual gland; this gland lies on the buccal surface of the mylohyoid muscle in the cleft produced by the gradual divergence of the hyoglossus and the mylohyoid muscles as they pass away from their attachments to the hyoid bone, the hyoglossus to join the tongue and the mylohyoid to be inserted into the mandible.

Fig. 4.—Section through middle of floor of mouth, fixed in solution of formaldehyde. *A*, sublingual gland and *B*, submaxillary gland.

Figure 3, from a specimen hardened in solution of formaldehyde, shows a frontal section of the mouth just back of the symphysis of the mandible; the sublingual salivary gland is seen on the buccal surface of the mylohyoid muscle.

Figure 4 is a frontal section about the middle of the mouth, showing the submaxillary salivary gland on the neck surface of the mylohyoid and the sublingual gland on its buccal surface (*A*). The fascia colli, forming the submaxillary capsule, has been emphasized on the right of the figure: it is attached to the mandible on both sides (superficial and

deep) of the submaxillary salivary gland (*B*) and surrounds the digastric muscle.

Figure 5 is a frontal section through the posterior part of the mouth, showing the free posterior border of the mylohyoid muscle (*A*), with the submaxillary salivary gland curling around it and with its uppermost portion lying in the sublingual space. The fascia colli, forming the submaxillary capsule, has been emphasized on the right side of the figure; one should note its attachment to the lower border of the mandible and to the hyoid bone (*C*), that it surrounds the posterior belly of the digastric

Fig. 5.—Section through posterior part of floor of mouth, fixed in solution of formaldehyde. *A*, mylohyoid muscle; *B*, facial artery and vein, and *C*, hyoid bone.

muscle (on which the submaxillary gland rests as on a shelf), and that it fades away on the surface of the hyoglossus muscle. *B* points to the facial artery (traversing the gland) and to the facial vein (in its capsule).

Figure 6 shows the left side of the floor of the mouth after resection of the body of the mandible, leaving in place the portions of the mandible to which the anterior and posterior limits of the left mylohyoid muscle are attached; the submaxillary salivary gland is seen curling around the posterior border of the mylohyoid, to enter the sublingual space where it becomes practically continuous with the sublingual salivary gland.

It is clear, then, as Moty pointed out, that when perforation of the outer plate of the mandible occurs, as is usual in mild infections arising from the bicuspid or anterior molar teeth, a dento-alveolar abscess forms (fig. 1). In dental infections arising from the back molar teeth or even from an unerupted wisdom tooth, perforation occurs through the internal plate or through the lower border of the mandible (figs. 4 and 5), the immediate result being a submaxillary cellulitis. From this situation infection may spread forward into the sublingual space,

Fig. 6.—Dissection showing mouth after resection of body of mandible, with submaxillary salivary gland curling around posterior border of mylohyoid. A section of the mandible was removed, from a little to the left of the symphysis to a point anterior to the left angle of the jaw, leaving attached to the inside of the mandible the anterior and posterior extremities of the left mylohyoid muscle. The drawing, from a dissection by the author, shows the anterior belly of the digastric detached and turned down (*A*); the cut edge of the left mylohyoid detached from the mandible (*B*) with the sublingual salivary gland (*C*) lying on its buccal surface (beneath the mucous membrane) and the submaxillary salivary gland (*D*) extending around the posterior free border of the mylohyoid and occupying both the neck and the buccal cavity; the facial artery (*E*) is retracted.

and downward and backward along the course of the facial and lingual arteries to the cellular tissue around the external carotid artery, that is, outside of the submaxillary capsule, and from here forward beneath the fascia colli (or even, after perforation of the fascia colli, in the subcutaneous cellular tissue) to the region between the chin and the hyoid bone. From the sublingual tissues on the side first affected, the infection may spread across the midline between the anterior part of the tongue and the mandible, thus gaining access to the sublingual and submaxillary spaces of the second side. From the region of the carotid vessels, the infection may spread to the fascias around the pharynx and the larynx. If the patient survives long enough, the entire cellular tissues of one or both sides of the neck down to the clavicles, and even into the mediastinum, may become infiltrated, as in case 11 recorded in this paper.

The infection of the tissues inside the submaxillary capsule does not always result in the extension of the infection to the sublingual tissues. A study of case 19 is interesting in this connection: This patient entered the hospital with a widespread cervical cellulitis due to dental infection, but without involvement of the sublingual tissues; these became infected only after incisions had been made from the neck into the mouth.<sup>29</sup> If these incisions had not been made, the infection might well have spread of itself to the sublingual tissues by the route around the posterior border of the mylohyoid.

#### EXPERIMENTAL INJECTIONS

In a certain number of experiments made in the Laboratory of Operative Surgery of the University of Pennsylvania, I have tried to demonstrate on the cadaver the routes by which this infection spreads. Using dilute chinese ink as a staining fluid, I have demonstrated the immediate spread of this stain from its point of injection under the mucous membrane covering the floor of the mouth in one gingivolingual sulcus. The first effect of such an injection of 40 or 45 cc. of the

---

29. Van Wagcnen and Costello (*Ann. Surg.* 87:684, 1928), in an interesting article on Ludwig's angina, classed eight of their cases as true or "primary" Ludwig's angina, while eight others they class as "secondary" Ludwig's angina. In the latter, they claimed that the primary infection was in the cervical tissues (outside of the submaxillary capsule) and reached the sublingual tissues not by the classic route (i. e., by extension around the posterior border of the mylohyoid), but by direct extension through the fibers of this muscle. This is perhaps a distinction without a difference. At any rate, many of their secondary cases are not convincing: they are cases seemingly of the same nature as their primary cases, only subacute in type. However, in one or two of their secondary cases the infection does seem to have gone into the sublingual tissues from the submental region across the fibers of the mylohyoid muscle. This perhaps is what occurred in case 14 as well as in case 19 of the present series.

Fig. 7—On June 1, 1928, 40 cc of dilute chinese ink was injected under the mucosa between the tongue and the alveolus on the right side of the mouth of a cadaver. The submucous tissues (on the right only) swelled visibly, raising the tongue up toward the palate. Immediate dissection of the neck showed the stain confined beneath the fascia covering the submaxillary salivary gland. The stain had spread down as far as the level of the middle of the thyroid cartilage. This drawing was made before further dissection. The platysma has been reflected up to expose the body of the jaw, showing the blue-black stain beneath the fascia covering the submaxillary salivary gland and spreading beneath this fascia down the neck as far as the level of the middle of the thyroid cartilage. The parotid gland is unstained.

solution is to raise the same side of the tongue against the palate. Almost simultaneously the dye appears in the submaxillary region beneath the fascia colli (fig. 7). If a greater quantity of dye is used, the stain soon traverses the fascia colli and also stains the platysma, the subcutaneous fat and even (in one case) a small area of the overlying skin. The stain was arrested posteriorly by the attachment of the fascia to the sternomastoid muscle; but the stain extended (very faintly) between the upper end of the larynx and pharynx almost to the midline of the body and spread up the anterior pillar of the fauces on the side on which the injection was made. It stained the thyrohyoid membrane forward to the midline. The under surface of the mylohyoid remained unstained, except at its posterior border; here the stain was dark and was continuous with that which infiltrated all the interstices of the submaxillary salivary gland and the sublingual tissues. The submaxillary salivary gland itself was not stained—only the fascia around its lobules. The stain followed the external maxillary artery from within the submaxillary capsule up on the surface of the masseter muscle. The stain did not extend appreciably beyond the midline, either within the mouth or in the neck. In one specimen (fig. 8), however, the stain, after extending across the sublingual tissues to the other side of the mouth, filled the submaxillary region on this side as well as on the side of the injection, and finally escaped from the submaxillary capsule along the course of the lingual artery into the neck on the other side of the cadaver from that in which the injection was made.

These few experiments merely serve to confirm what was already known of the spread of the infection from clinical observation.

#### TREATMENT

I shall have little to say under this head, except that (1) once the diagnosis of Ludwig's angina has been made, no time should be lost in instituting drainage of the parts affected, and that (2) incisions for providing drainage should be made in certain definite locations, not in a haphazard way.

*Early Incisions.*—When cellulitis occurs in other situations, especially in the limbs, early incisions, though important and usually too long deferred, are not so imperative as they are in cases of Ludwig's angina. Even when cellulitis of the neck (not Ludwig's angina) is seen, it may be safe to temporize and to employ cold applications followed by poultices until suppuration is suspected (case 19). But a patient with Ludwig's angina is threatened with suffocation; his tongue is pushed up against the roof of his mouth, and he has to keep his mouth open as far as the trismus will permit, in order to allow access of air to his lungs by way of his nose through the narrow chink which may still persist

between the root of the tongue and the soft palate, anteriorly, and the posterior wall of the pharynx behind (fig. 10). Tracheotomy is sometimes necessary, not because of edema of the glottis (as far as my observation goes), so much as because the air way is blocked off by the elevated and swollen tongue. Incision of the swollen tissues when made in the definite way to be described at once relieves the swelling in the neck and in the floor of the mouth, and the patient is relieved of

Fig. 8.—Section (sagittal plane) fixed in solution of formaldehyde to show stain spreading to opposite side from that on which injection was made. *A* indicates the hyoid bone.

the dyspnea within a few hours without resort to tracheotomy; hence, the latter operation is to be considered only in patients already almost moribund.

*Sites of Incisions.*—(*a*) The first incision should be made in the midline between the chin and the hyoid bone, and the knife should pass directly through the median raphe into the gingivolingual sulcus just back of the symphysis. Into the tract (for it need be little more than a puncture) thus made, a long curved forceps is passed; its jaws are made to emerge between the teeth, and a per-

forated rubber tube is drawn down from mouth to neck. Each end of this tube (one end beneath the tip of the tongue, and the other at the skin level beneath the chin) is transfixed by a safetypin.

(b) The second incision is to be made anteroposteriorly well below the angle of the jaw of the side affected, about 4 or 5 cm. long, but through the skin and platysma only. A long curved forceps is then thrust into this incision, traverses the submaxillary space, and is brought out through the mucous membrane at the side of the tongue opposite the molar teeth. A second perforated rubber tube is grasped by this forceps and is pulled through to the neck, and a safetypin is placed in each end of the tube.

(c) The third incision, not usually required, is in all respects similar to the second but is on the opposite side of the neck. When the patient is first seen by a surgeon, the disease has seldom spread to the second side of the neck; if the two incisions first described are promptly made, the disease usually is arrested.

Fig. 9 (case 13).—A, appearance of patient on admission. B, incisions and drainage tubes. (From the Episcopal Hospital.)

These incisions may be made by anyone, without fear of causing hemorrhage or injury to the nerves. In desperate cases, they may be made even without any anesthetic. In most cases, however, there is no objection to the local use of procaine hydrochloride by infiltration in the skin, or by blocking the superficial cervical plexus at the posterior border of the sternomastoid muscles, as advised by van Wagenen and Costello. Only the skin needs to be anesthetized, as I have found the deeper tissues not sensitive. A general anesthetic is seldom advisable. The entire operation occupies only a few minutes.

The incisions described were first systematized, as far as I know, by the late Gwilym G. Davis, and they have been employed, with great satisfaction, in most of the cases of the disease encountered at the

Episcopal Hospital. I believe that it is unnecessary to make a formal dissection exposing the mylohyoid muscle, as has been advocated by a number of surgeons; if a drainage tube is carried across the edematous tissues from mouth to neck in the two (rarely three) situations mentioned, by the simple process I have described, the edema will rapidly subside. One can almost see the swelling decrease as he watches by the patient's bedside.

As a dressing, I employ abundant fluffed gauze, dripping with a hot solution (2 per cent) of sodium citrate; this dressing is covered with waxed paper to keep it moist and is changed as often as it becomes

Fig. 10 (case 18).—Appearance of patient just before operation. (From the Episcopal Hospital.)

soiled. Frequent irrigation through the tubes with saline solution encourages drainage.

Pus is not always encountered in making these incisions, simply because it has not yet formed. When it does form it will be found soonest in one or the other, or in both, of the sites traversed by the drainage tubes. If the incisions are made promptly, the stage of supuration may be prevented from developing.

Careful nursing and cautious feeding are required. Fluids may be given by rectum or subcutaneously, until the patient can swallow. Pulmonary complications are to be feared and guarded against. Most patients, however, die from sepsis, not from edema of the glottis or pneumonia.

Of the eighteen patients observed at the Episcopal Hospital, five died, a mortality of 27.7 per cent. The causes of death were:

CASE 11.—Death occurred twenty-four hours after admission. Prodromes were noticed seven days before admission, and swelling of the tongue four days before admission. The patient was semiconscious from sepsis on admission. Tracheotomy was performed for respiratory obstruction. Autopsy showed infection of the floor of the mouth extending into the mediastinum; pulmonary edema and congestion were present. A three months' empty gravid uterus was found.

CASE 12.—Death occurred one and one-half hours after admission. Prodromes were noticed four days before admission, swelling of the neck two days before admission and dyspnea for the last twenty-four hours. The chief complaint was asphyxia. Incisions were made as described in the text, but as improvement did not occur within an hour, tracheotomy was done. Autopsy was not performed. Death was caused by asphyxia and sepsis.

CASE 15.—Death occurred forty-eight hours after admission. Swelling underneath the tongue was noticed four days before admission; this was quickly followed by swelling of the neck. At 5 p. m., incisions were made on both sides of the neck, as described in the text. Tracheotomy was done thirty-two hours after admission, without improvement; death occurred sixteen hours later, from sepsis. Autopsy was not performed.

CASE 16.—Death occurred five days after admission. The onset occurred four days before admission. Three incisions were made, as described in the text. The patient did well, but three days later nearly died from myocardial failure; he rallied, but death occurred from renewed heart failure due to sepsis five days after admission. Autopsy was not performed.

CASE 18.—The patient died about fifteen hours after incision and drainage, in uremic convulsion; autopsy was not performed.

Cultures were made in some of these cases and, as in most of the others reported, showed streptococci as the predominating organisms, with many other bacteria derived from the buccal cavity. In cases 6 and 18, however, a pure culture of staphylococcus was grown.

In addition to the histories of the eighteen cases of Ludwig's angina, I have appended four other case histories:

CASE 19.—This case was an instance of cervical cellulitis following extraction of teeth; it cannot be properly classed as Ludwig's angina, though the latter syndrome did actually develop following incisions made into the floor of the mouth for the purpose of draining the cervical region. As the incisions made were those designed for the relief of Ludwig's angina, great alarm was not experienced when sublingual cellulitis developed within the next twenty-four hours after operation, as I felt certain it would promptly yield to drainage along the tracts already made. This proved to be the case, and uneventful recovery followed.

CASE 20.—This case was an example of massive abscess of the neck caused by suppurative submaxillary lymphadenitis due to infection from the tonsils. It was in no sense a case of Ludwig's angina.

CASE 21.—This case was one of suppurative submental lymphadenitis, secondary to some unrecognized intrabuccal lesion. If this lymphadenitis had gone unrelieved, it might have extended directly into the sublingual tissues, thus causing what van Wagenen and Costello have classed as secondary Ludwig's angina.

CASE 22.—This case was one of sublingual cellulitis following trauma, with cellulitis of the soft palate. The infection never spread to the submaxillary or cervical regions, though these participated slightly in the traumatic edema, and the case cannot be considered one of Ludwig's angina.

## REPORT OF CASES

### LUDWIG'S ANGINA

CASE 1 (Drs. Frazier and Havens).—*History*.—Samuel B., aged 61, was admitted to the hospital on Nov. 11, 1905, and had recovered by Nov. 20, 1905. After several days of discomfort from a loose tooth, eight days before admission he noted considerable pain in the lower jaw, followed by extremely hard swelling under the chin, with difficulty in breathing and swallowing. Weakness, slight fever but no chill were present.

On admission, there was hard swelling under the chin extending down to the larynx. The breath was extremely offensive. Redness and swelling were present under the tongue. One loose tooth, the cause of the trouble, was still in place. The patient experienced difficulty in swallowing and breathing. The temperature was 100.4 F.; the pulse rate, 108, and respirations, 20.

*Treatment and Progress*.—Three openings were made in the swollen neck, a hemostat being thrust in in various directions. A little thin, watery, offensive material escaped, but pus was not found. Two rubber drain tubes were left in place.

Recovery was uneventful; the patient returned home after nine days.

CASE 2 (Drs. Neilson and Price).—Thomas C., aged 29, was admitted to the hospital on April 21, 1908. Recovery occurred. This case was reported by Price.<sup>23</sup>

CASE 3 (Drs. Neilson and Price).—Joseph D., aged 22, was admitted to the hospital on May 4, 1908. Recovery occurred. This case was reported by Price.<sup>23</sup>

CASE 4 (Drs. Neilson and Price).—Carrie B., aged 16, was admitted to the hospital on May 12, 1908. Recovery occurred. This case was reported by Price.<sup>23</sup>

CASE 5 (Drs. Davis and Brown).—*History*.—Charles Carr, aged 83, was admitted to the hospital on Feb. 8, 1909. Recovery occurred. While in the hospital, the patient died of senility on March 29, 1909. Seven weeks before admission, he had a tooth extracted from the right lower jaw, which became swollen and painful; the swelling under the jaw had increased.

On admission, the man was well nourished but mentally confused. Under the mandible, the tissues were red, swollen and hard; some swelling was present under the tongue. Pus was exuding from a socket of a tooth extracted seven weeks before admission. The temperature was 97.6, the pulse rate, 84, and respirations, 24.

*Treatment and Progress*.—A mouth wash and a tonic were given.

On February 14, the swelling in the mouth had disappeared. On February 16, the swelling and induration were entirely gone; the mental condition was poor. This condition continued, without fever or local symptoms, until death seven weeks after admission.

CASE 6 (Drs. Neilson and Newell).—*History*.—George D., aged 27, was admitted to the hospital on May 27, 1909, and had recovered by June 8, 1909. The patient had had tonsillitis several times and frequent toothaches and sore gums. The teeth had never had proper attention. Five days before admission, the patient developed swelling of the gums on the right side of the lower jaw, outside of the

teeth; soreness was not present at first, but he felt bad all over and could not eat. The next day swelling of the neck commenced and became progressively worse. The patient could neither sleep, eat nor swallow and had severe headache.

On admission, the chief complaint was painful swelling under the jaw, swelling in the mouth and inability to swallow. The neck was greatly swollen anteriorly; the swelling was tender but not red and did not fluctuate. The floor of the mouth was swollen level with the crown of the lower incisor teeth. The patient had dyspnea, could not swallow, and was apparently in great pain. The temperature was 100, the pulse rate, 100, and respirations, 24.

*Treatment and Progress.*—An incision was made below the chin in the midline (not through into the mouth) and a counter incision below the angle of the right mandible. A rubber tube was drawn through and through. A pure culture of staphylococcus was obtained. On June 2, 1909, the tube was removed. On June 6, swelling or tenderness was not present. On June 8, the patient went home.

CASE 7 (Drs. Deaver and Ivy).—*History.*—Joseph M., aged 11 months, was admitted to the hospital on July 26, 1909, and had recovered by Aug. 16, 1909. On admission, induration and swelling of the submaxillary triangles, especially the right, were present, but no undue redness. The floor of the mouth was infiltrated and on a level with the alveolar border; it was indurated on the right side, and soft on the left. The points of the lower central incisors were seen, just erupting. The throat was clear. The child put its hands to its neck as if in pain. The temperature was 102, the pulse rate, 144, and respirations, 40.

*Treatment and Progress.*—Under chloroform anesthesia, an incision was made in the median line under the chin and a counter incision in the right submaxillary triangle toward the angle of the jaw; incisions were also made through the deep fascia; clear fluid and blood were evacuated, but no pus. A rubber tube was passed between the two incisions.

On July 31, the floor of the mouth was almost normal. The tube was replaced by iodoform gauze. The patient made an uneventful recovery and was taken home on August 16.

CASE 8 (Drs. Mutschler and Gage).—*History.*—Michael K., aged 55, was admitted to the hospital on April 23, 1918, and had recovered by April 30, 1918. A tooth was extracted on April 17; on April 20 "swelling of the floor of the mouth started, and also some swelling in the neck."

On admission, the chief complaint was "extreme sore throat and inability to swallow food, also diffuse swelling in the neck around the region of the mandible." The temperature was 99, the pulse rate, 96, and respirations, 24.

*Treatment and Progress.*—A mouth wash was used and an ice pack applied to the neck. On April 25, the patient felt somewhat better; the swelling was hard and diffuse in the region of the neck. On April 28, he was much better; a flaxseed poultice was applied every hour to the neck. On April 29, he was "unable to get drainage in the mouth, so the neck was lanced and a drainage tube inserted." On April 30, he was discharged in good condition at his own request.

CASE 9 (Drs. Ashhurst and Lew).—*History.*—Robert S., aged 4 years, was admitted to the hospital on Dec. 29, 1920, and had recovered by Jan. 6, 1921. A tooth was extracted the day before admission. The child cried all that night. He did not cough. He could not speak or swallow.

On admission, the chief complaint was swelling of the lower jaw. "Tongue is swollen and protruding up, and touching the hard palate. The floor of the mouth is markedly swollen. No fluctuating area felt, does not feel hard. The left side

of the face is more swollen than the right." The temperature was 101.6, the pulse rate, 120, and respirations, 24.

*Treatment and Progress.*—Immediate operation (at 2:25 p. m.) was performed under local procaine hydrochloride anesthesia (Dr. Ashhurst). The time required was fifteen minutes. An incision was made in the midline of the neck just posterior to the chin; a hemostat was inserted and pushed through the median septum into the mouth just back of the central incisors, and a small rubber tube drawn through and fixed by a safetypin at each end. A second incision was made through the skin and fascia in the left submaxillary region; the hemostat was pushed into the cavity of the mouth, and a second rubber tube drawn through and fixed by a safetypin at each end. Pus was not found, only a serosanguineous exudate.

In a few hours after the operation, the patient was able to swallow. He slept well. On December 31, the swelling in the floor of the mouth was gone; the tubes were cut off flush with the floor of the mouth, the excess of tubes with the safetypins being removed. The remainder of the tubes was left protruding from the neck. On Jan. 2, 1921, the tubes were removed entirely. On January 3, the patient was normal except for the healing incisions in the neck. On January 6, he went home.

CASE 10 (Drs. Deaver and Ross).—*History.*—James D., aged 46, was admitted to the hospital at midnight, Dec. 26, 1923, and had recovered by Jan. 5, 1924. He first noted trouble in swallowing on December 26. There was no definite history of any injury to the tongue. The pain in swallowing persisted, and in the afternoon he noticed that the tongue was enlarged. Dr. W. B. Scull saw him about 6 p. m., and as he became progressively worse, Dr. Scull was called to see him again about midnight; at his first visit Dr. Scull could examine the throat, and found the tonsils inflamed; at the second visit, he could not open the mouth enough to examine the throat, and the patient was gasping for breath. At this time he was sent to the hospital.

On admission, the patient was able to walk to bed, but had great pain and discomfort in the neck and in the floor of the mouth. Breathing was audible and labored. The breath was especially foul and had the odor of alcoholic liquor. The tongue was swollen, red and dry and was pushed upward and backward from the roof of the mouth. The cellular tissues about the tongue and floor of the mouth were edematous, and a perforation was present in the right side of the floor of the mouth. The teeth were bad. Saliva was dribbling from the mouth. The pharynx could not be brought into view. Induration of the cellular tissues below the jaw on either side, particularly on the left, extended downward between the mandible and the clavicle. The swelling was tender, but not red or inflamed. The temperature was 103, the pulse rate, 124, and respirations, 48.

*Treatment and Progress.*—Dr. Ross at once instituted through-and-through drainage from the floor of the mouth to the submental region, and between the two sides of the neck through the mylohyoid muscle.

On December 27, the patient had improved. He had an attack of dyspnea at 4 p. m., which subsided of itself. On December 28, not much discharge came from the tube; flaxseed poultices were applied. On December 30, the drainage was removed. On Jan. 4, 1924, there was much better motion of the jaw and less swelling. On January 5, the patient was discharged and was referred to the dental dispensary.

CASE 11 (Drs. Alexander and Bush).—*History.*—Dorothy R., a negress, aged 16 years, was admitted to the hospital on July 9, 1924, and died on July 10.

Seven days before admission, this girl complained of pain in the epigastrium, and soreness of the throat and tongue, and was unable to pass urine. Four days before admission, the tongue began to swell, and the day before, the face began to swell. The tongue and mouth had been covered with ulcers for the last three days.

On admission, the chief complaint was swelling of the tongue. She lay flat on her back, breathing with great difficulty. The eyes were widely dilated, the lips greatly swollen, and the tongue protruded between the lips and was swollen to about four times its natural size. On the under surface of the tongue along the sides of the mouth were many ulcers. As the girl breathed, mucus bubbled from the mouth. The odor was offensive. The cheeks were swollen. Below the jaw, out to its angle on either side, was a large area of extremely hard swelling. The patient was semiconscious and had an anxious expression. The swelling under the jaw extended down the neck and backward on both sides. The thyroid was not enlarged; cervical adenopathy was not present.

The chest was well developed and symmetrical; the respirations were rapid and spasmodic, and there was marked recession of the interspaces on inspiration. The temperature was 103.4, the pulse rate, 120, and respirations, from 28 to 32. The leukocytes numbered 11,120 and 11,400, on two counts, with 80 per cent polymorphonuclears.

*Treatment and Progress.*—Low tracheotomy was done, which relieved the dyspnea.

On July 10, the patient was blowing purulent material through the tracheotomy tube. She died about noon.

*Autopsy* (Dr. C. Y. White).—The infection of the floor of the mouth extended into the mediastinum. Old pleural adhesions, pulmonary edema and congestion and acute diffuse nephritis were present. A three months' empty gravid uterus was found. Passive congestion of the spleen was present. The cervical and anterior mediastinal lymph nodes were enlarged. The submaxillary salivary glands were not involved. The mammary glands were hypertrophied.

CASE 12 (Drs. Ashhurst and Hicks).—*History.*—Peter F., aged 29, was admitted to the hospital on Dec. 20, 1924, and died one and one-half hours later.

Four days before admission he refused to eat, saying that he felt cold. He did not feel pain. Three days before admission, he was unable to go to work, but refused to consult a physician. Two days before admission, a swelling appeared under the jaw on the right side. The swelling grew worse and extended around the jaw and down the neck. The day before admission he stopped talking and also began to have difficulty in breathing. Dyspnea and swelling continued to increase, and that night a physician was consulted for the first time; he advised immediate removal to the hospital.

On admission, the patient walked into the receiving ward with the aid of friends; the respiratory difficulty was so great that he was evidently dying; there was indrawing of the costal margins and interspaces during inspiration. He was unable to speak, the eyes were protruding, and there was slight cyanosis. He was unable to close the mouth, and the tongue was pushed against the roof of the mouth. Bilateral swelling of the neck below the jaw was present; this swelling was of boardlike consistency and extended well down toward the sternum. The temperature was 100.8, pulse rate, 100, and respirations, 24.

*Treatment.*—At operation (Dr. Hicks), an incision was made from the submental region into the floor of the mouth, and a rubber tube was pulled through and through. An incision was made in each submaxillary region and was connected by rubber tube drainage; also, a drainage tract was made from each sub-

maxillary region into the floor of the mouth. Improvement did not occur. Tracheotomy was done. Death occurred one and one-half hours after admission. Autopsy was not performed.

CASE 13 (Drs. Ashhurst and Zemp).—*History*.—Christopher D., aged 23, was admitted to the hospital on Sept. 20, 1925, and had recovered by Oct. 5, 1925.

Two weeks before admission, a tooth was pulled from the right upper jaw, and this had not caused any discomfort since. On awakening on the morning of September 19, he noticed that he had bitten his tongue during his sleep and that it was greatly swollen. At 1 p. m., he noticed swelling at the right angle of the jaw; he could open his mouth, but had some difficulty in swallowing. The tongue continued to swell and pushed upward to the roof of the mouth. The patient consulted a physician during the afternoon, who gave him a plaster to apply to the neck. The next morning he was worse, and his physician sent him to the hospital.

On admission, the chief complaint was difficulty in swallowing. The tongue was greatly swollen; the tissues beneath the tongue were inflamed and swollen, and the tongue pushed upward toward the roof of the mouth. The tonsils did not appear diseased. The neck showed pronounced swelling on the right, below the mandible, extending from the submental region to the angle of the jaw; slight swelling was present on the left. The swelling was firm but not red. The temperature was 99.6, the pulse rate, 72, and respirations, 16 (fig. 9).

*Treatment and Progress*.—Operation was performed under local procaine hydrochloride anesthesia (Dr. Ashhurst); the time required was twelve minutes. An incision, 1 cm. long, was made in the midline below the chin, a scalpel being passed through to the floor of the mouth just behind the symphysis; a curved hemostat was passed through the same wound into the mouth, and a rubber tube drawn through and through. A second incision, 3 cm. long, was made below the angle of the mandible on the right, through the skin and fascia; a curved hemostat was passed through this incision into the mouth posterior to the mylohyoid, and a rubber tube pulled through and through. Pus was not found. A safety-pin was fixed in both ends of each tube. A dressing immersed in hot sodium citrate (2 per cent) was applied.

On September 21, the dressings were changed frequently, and the incisions drained freely throughout the night. The swelling had subsided to some extent, and the patient drank water freely. On September 22, the condition was greatly improved; the swelling was subsiding. A purulent discharge with a foul odor came from the tubes. On September 24, the tubes were replaced by smaller ones. The patient could drink more easily and could move his tongue better. On September 26, the swelling was almost gone; a foul purulent discharge came from the tubes. On September 29, though the patient had been up in a wheel chair for several days, he fainted when shown to the ward class. On October 3, the tubes were removed; a slight purulent discharge came from the incisions. On October 5, the patient went home; there was no discharge from the incisions.

CASE 14 (Drs. Ashhurst and Zemp).—*History*.—Marie E., aged 30, was admitted to the hospital on Oct. 26, 1925, and had recovered by Nov. 14, 1925. About four days before admission she began to develop a swelling below the chin, with increasing difficulty in swallowing and talking, and on the day of admission became unable to breathe lying down. She had been treated with sulphonated bitumen, N. F. and flaxseed poultices.

On admission, the chief complaint was difficulty in swallowing. The tongue was up against the hard palate, and marked induration of the floor of the mouth was present; the submental region was considerably swollen and tender, but was

not red and did not fluctuate. A small pimple was present on the left side of the chin. Swelling was not present on either side of the submental triangle. The temperature was 101.4, the pulse rate, 96, and respirations, 22. The white blood cells numbered 11,120 with 77 per cent polymorphonuclears.

*Treatment and Progress.*—At 2:30 a. m., the time of admission, while the patient was under local anesthesia, a submental incision was made and a drain tube carried through to the floor of the mouth back of the symphysis.

There was steady improvement during the day of admission; the tube discharged foul purulent material; the breathing was better, and the swelling was not so great. Hot sodium citrate (2 per cent) dressings were changed every hour. On October 27, the condition was greatly improved; the swelling was less; a foul purulent discharge came from the tube. On October 28, the patient was somewhat better, but the swelling in the submental region was more pronounced and had spread on each side to the submaxillary regions, which were hard.

At a second operation (Dr. Ashhurst), under local anesthesia, an incision 3 cm. long was made just in front of and below the angle of the jaw on each side, and a hemostat pushed through into the mouth posterior to the mylohyoid. On the right side, a large quantity of foul smelling pus was evacuated; pus was not found on the left. A safetypin was fastened on the ends of each tube. On October 29, there was a slight break in the temperature; a slight purulent discharge came from the tubes. The condition was somewhat improved; the tongue was not pushed up quite so high. On the afternoon of October 30, the temperature broke; the patient was much better. On November 1, the tongue was returning to its normal position and the swelling was much less; the discharge was more purulent. The three rubber tubes were replaced by smaller ones. The patient took liquids by mouth more easily. On November 4, the tubes were removed. On November 14, she could open the mouth and move the tongue normally. Slight induration was present on the right side. A slight discharge came from the median incision. The patient went home.<sup>30</sup>

CASE 15 (Drs. Deaver and Headings).—*History.*—Clementine K., aged 61, was admitted to the hospital on May 28, 1926, and died on May 30, 1926. Four days before admission she developed pain and swelling underneath the tongue, which increased until at the time of admission there was marked swelling about the neck; this caused great difficulty and pain in swallowing, and grew rapidly larger every few hours.

On admission, the temperature was 100, the pulse rate, 72, and respirations, 24. The leukocytes numbered 26,560. The blood pressure was 170 systolic; 95 diastolic. The tongue was white and furred, and somewhat swollen, and did not protrude beyond the lips. The tonsils were not seen. The neck was markedly swollen in both submaxillary regions and was hard and slightly tender on pressure.

*Treatment and Progress.*—Operation (Dr. Deaver) was performed at 5 p. m., while the patient was under nitrous oxide anesthesia. An incision 5 cm. long was made beneath the angle of the jaw and parallel to the jaw; enlarged submaxillary glands were felt, and the tissues about the glands were edematous and filled with

30. This case probably corresponds to those which Van Wagenen and Costello class as "secondary Ludwig's angina." Perhaps the original submental swelling was a lymphadenitis, secondary to the "pimple" on the chin. Before admission, however, the floor of the mouth was attacked by cellulitis, and subsequently both submaxillary regions were invaded by cellulitis, probably spreading downward from the sublingual tissues by the route around the posterior border of the mylohyoid.

fluid. A hemostat was introduced into the floor of the mouth and was brought out beneath the submaxillary gland. This was done on the other side also. A smear showed streptococci, staphylococci, diplococci and bacilli.

On May 30, 1926, the patient breathed with difficulty. Tracheotomy was done at 1:45 p. m. The patient died at 5 p. m., forty-eight hours after admission.

Autopsy was not performed.

CASE 16 (Drs. Ashhurst and Lynch).—*History*.—Eugene H., aged 40, was admitted to the hospital on May 21, 1927, and died on May 26, 1927. Three days before admission, a lower right wisdom tooth was extracted. The same night he had a chill, and the neck and floor of the mouth began to swell on both sides, becoming progressively larger, and causing more and more difficulty in swallowing. The patient was unable to sleep because of difficulty in breathing. He was seen by a physician on May 20 and was sent to the hospital about 2 p. m. on May 21.

On admission, the chief complaint was swelling of the neck and floor of the mouth. The temperature was 102.6, the pulse rate 110, and respirations, 24.

Showers of granular casts were found in the urine. The eyeballs were slightly prominent. The patient was unable to open the mouth more than 1.5 cm. The teeth apparently were normal. The tongue was coated. The tonsils were not visible. The floor of the mouth was extremely edematous. The neck was edematous and hard on both sides; it was red on the right and moderately red on the left.

*Treatment and Progress*.—Operation (Dr. Ashhurst) was performed at 2:25 p. m. while the patient was under nitrous oxide gas anesthesia. The time required was fifteen minutes. Three incisions were made, each about 2 cm. long, in the submental and in each submaxillary region. Curved forceps were thrust through each of these incisions into the mouth, and a rubber tube was pulled through each tract; a safety-pin was fastened in each end of each tube. Pus was obtained only from the incision on the right.

On May 22, the tubes were draining freely; the edema of the neck had decreased; the patient was able to take fluids by mouth. The general condition was improved. The edema of the floor of the mouth was less.

On May 23, the patient coughed a good deal and was irrational at times. The general condition was worse.

On May 24, the tubes were draining a good deal. The edema of the floor of the mouth had disappeared; the edema of the neck was less. The general condition was the same. The patient nearly died that night from myocardial failure. Violent stimulation revived him.

On May 25, another puncture was made low in the left side of the neck (without an anesthetic), and a little pus was obtained by running the hemostat up toward the left submaxillary incision. The rest of the neck was soft. The tubes were withdrawn below the level of the mouth.

Early on the morning of May 26, the patient went into collapse again (heart failure from sepsis) and died at 1:30 p. m., without a reaction. There was no evidence of pressure on the larynx or on the trachea from the outside, or of edema of the glottis. The temperature was 106 F. at death.

Autopsy was not performed.

CASE 17 (Drs. Deaver, Weber and Baker).—*History*.—Margaret O., aged 33, was admitted to the hospital on Jan. 18, 1928, and had recovered by Feb. 4, 1928. Five days before admission she felt bad and had a chill; pain and swelling about the chin soon developed. The physician ordered a local application of ointment. Since the pain and swelling continued to increase, the patient was referred to the hospital.

On admission, the chief complaint was pain and swelling of the chin and the left side of the face. The temperature was 102.4, the pulse rate, 156, and respirations, 28. The patient lay quietly in bed and did not have dyspnea or cyanosis. Marked swelling, redness and tenderness were present over the chin and the neck and extended upward over the left side of the face. The tissues were reddened, thickened and brawny, especially about the region of the floor of the mouth. A sharp line of demarcation was not seen. A few vesicles were present over the left side of the face at the upper border of the swelling. The left eyelid was somewhat swollen and the conjunctiva reddened. The patient could not open the mouth widely enough for a thorough examination, but the tissues of the mouth were markedly swollen.

*Treatment and Progress.*—Operation (Dr. Weber) was performed at 2 p. m., while the patient was under ether anesthesia.

Two longitudinal incisions were made about 1 inch (2.5 cm.) to the right and to the left of the midline; the muscle was exposed; a hemostat was inserted into the wound and opened, allowing the escape of a small amount of pus. The incision was made deeper by blunt dissection and was carried into the floor of the mouth. A rubber tube was inserted in each incision, extending into the mouth. A smear showed short chain streptococcus.

On January 19, the inflammation extended upward over the face and eyes and the left ear. The left ear was covered with large vesicles containing yellowish watery fluid. Small vesicles were present over the left side of the cheek. The left eye was closed. Only a small amount of material drained from the tubes in the neck. The patient appeared toxic; she was given 50 cc. of antistreptococcic serum intravenously.

On January 20, the toxicity was gone, and the temperature dropped to 99.4 F. The local condition did not show improvement.

On January 21, 50 cc. of antistreptococcic serum was given intravenously.

On January 25, the inflammation was subsiding over the face and neck, but had spread over the entire upper part of the thorax. The temperature was 103 F. The general condition continued to improve.

On January 31, the incisions had practically healed, and on February 4, the patient went home.

CASE 18 (Drs. Deaver, Knox and Heise).—*History.*—Gertrude M., aged 33, was admitted to the hospital on Oct. 15, 1928, and died on Oct. 21, 1928. Self induced abortion when she was two months pregnant had resulted in infection two weeks before admission. Vomiting and fever were present for ten days before admission. On admission, the patient was in a septic and uremic condition (blood urea, 229.5 mg. per hundred cubic centimeters of blood), and had an aortic regurgitant murmur. The uterus was evacuated on October 17. On the morning of October 20, the tongue was found swollen and the floor of the mouth infiltrated with inflammatory exudate; the patient held the mouth open, and a sublingual mass of hemorrhagic necrotic tissue was present. After consultation, I confirmed the diagnosis of Ludwig's angina; I found swelling in both submaxillary regions, worse on the left, and also beneath the chin (fig. 10).

*Treatment and Progress.*—Operation (Dr. Knox) was performed on Oct. 20, 1928, while the patient was under local anesthesia. Small incisions were made (through the skin and fascia only) beneath the chin, and in each submaxillary region, and blunt forceps were thrust through the intervening tissues into the floor of the mouth; a rubber tube was pulled through each of the incisions from the mouth to the neck and each end fixed with a safety pin; dressings immersed in hot solution of sodium citrate were applied to the incisions.

On October 21, the patient died in uremic convulsion at 5:30 a. m.; there was no evidence of respiratory embarrassment from the cellulitis of the mouth and neck. Autopsy was not performed.

#### CONDITIONS OTHER THAN LUDWIG'S ANGINA

CASE 19 (Drs. Ashhurst and Lynch).—*Cellulitis of neck following extraction of teeth.*

*History.*—Elsie S., aged 20, was admitted to the hospital on Feb. 15, 1927, and had recovered by Feb. 25, 1927. Four days before admission three teeth were extracted from the left lower jaw, and two teeth from the right lower jaw. Three days before admission, the jaw became swollen; within twenty-four hours the swelling was much worse; it was red and so painful that the patient could not sleep. She was first seen by a physician on February 14, and because the condition had not improved by the next day she was sent to the hospital.

On admission, the chief complaint was pain and swelling of the jaw. The temperature was 101 F., the pulse rate, 104, and respirations, 26. The leukocytes numbered 15,800, 75 per cent of which were polymorphonuclears. The patient was unable to open the mouth more than 2 cm. The tongue was heavily coated but protruded normally. The breath was foul. The folds of mucous membrane under the tongue were edematous and extremely congested and along the margins of the mandible appeared almost gangrenous. The last bicuspid and the first and second molars on the left, and the first and second molars on the right had been removed. An exudate covered the alveoli. It was impossible to open the mouth enough to see the tonsils. Beneath the mandible and down to the hyoid bone a great deal of swelling was present. The area was reddened and hard and somewhat more swollen on the right. The diagnosis (Dr. Ashhurst) was: "Cellulitis of neck, following tooth extraction. There is no cellulitis or swelling of the floor of the mouth and it is not a case of Ludwig's angina."

*Treatment and Progress.*—An ice bag was applied to the neck continuously for twenty-four hours; then flaxseed poultices were used for forty-eight hours. On February 18, there was less edema and redness; no fluctuation; cellulitis under the tongue had not yet appeared. The temperature ranged from 101 to 102 F. On February 19, operation (Dr. Ashhurst) was performed while the patient was under local procaine hydrochloride anesthesia. A small incision was made beneath the chin, and another small incision on the left below the body of the mandible; a curved forceps was forced upward through each incision into the mouth just inside the teeth, and a rubber tube was drawn through each incision from the mouth to the neck. In the midline incision about 15 cc. of pus was found midway between the surface of the skin and the floor of the mouth (i. e., superficial to the mylohyoid muscle). Pus was not found in the lateral incision. The patient did not sleep that night.

On February 20, there was a good deal of purulent drainage. In the morning the tongue and sublingual tissues were swollen, just as in cases of Ludwig's angina; this was evidently due to infection carried in along the drainage tracts from tissues superficial to the mylohyoid muscle. The patient complained of a great deal of pain. The temperature was 103 in the evening. As the incisions already made were adequate for drainage in cases of Ludwig's angina, further incisions were not made.

On February 21, the condition was slightly improved. On February 22, it was greatly improved. Intrabuccal portions of the drain tubes were cut off. On February 24, the temperature was normal. On February 25, the drains were

removed; some purulent discharge came from the incisions. The patient went home in good condition.

CASE 20 (Drs. Mutschler, Davison and Storm).—*Suppurative submaxillary lymphadenitis.*

*History.*—Louis S., aged 21, was admitted to the hospital on June 19, 1926, and had recovered by July 4, 1926. He was entirely well until four days before admission, when he noticed a slight swelling under the angle of the right jaw, accompanied by pain. The swelling began to grow more tense and to extend upward and under the chin until it reached its present size. The patient felt considerable pain and had been unable to take any solid food for the past two days. He had not had any trouble with his teeth.

On admission, the chief complaint was a lump on the right side of the face (fig. 11). The temperature was 100.6 F., the pulse rate, 72, and respirations, 18. The leukocytes numbered 17,600, with 88 per cent polymorphonuclears.

Fig. 11 (case 20).—Suppurative cervical lymphadenitis caused by infection from the tonsils. (From the Episcopal Hospital.)

The patient lay in bed, complaining of pain in the right side of the jaw. The scalp was normal, and the nose and ears were grossly normal. The teeth were in excellent condition, and the patient did not have pyorrhea. The tongue was moderately coated and protruded normally. He was not able to open the mouth further than  $\frac{1}{2}$  inch (1.2 cm). The tonsils were hypertrophied, and several caseous areas were noted, especially on the right tonsil. There was marked swelling over the right side of the neck, extending from the chin to the angle of the mandible; it was about the size of an orange, hard and indurated, warm and red. No other adenopathy was noted. The diagnosis was adenitis of the right side of the neck.

*Treatment and Progress.*—Operation (Dr. Davison) was performed while the patient was under local anesthesia by procaine hydrochloride infiltration. An incision, 2.5 cm. long, was made beneath the mandible; a hemostat was inserted as far

as the mandible through hard and indurated tissue, free pus being obtained. Rubber tissue drains were inserted, and flaxseed poultices were applied.

On June 20, there was free discharge of pus; the temperature was normal. On June 21, the temperature was 103 F.; the wound was probed, a small amount of pus being found. On June 23, the temperature was 102 F.; the wound was probed and another incision made. On July 4, the patient had recovered and went home.

CASE 21 (Dr. Ashhurst).—*Submental suppurative lymphadenitis.*

*History.*—Carrie W., aged 2½ years, was admitted to the surgical dispensary of the Children's Hospital of Philadelphia on Sept. 7, 1908, and had recovered by Sept. 19, 1908. From some unrecognized intrabuccal lesion, this child developed a submental swelling. Several days later, when she was first brought to the dispensary the source of infection was not evident. Incision and drainage of the abscess (Dr. Ashhurst), with daily dressing for several days, resulted in prompt recovery. Ten days after she was first seen she was dismissed, cured (fig. 12).

Fig. 12 (case 21).—Suppurative submental lymphadenitis, caused by intrabuccal lesion. (From the Children's Hospital of Philadelphia.)

CASE 22 (Drs. Neilson and Pratt).—*Sublingual cellulitis; cellulitis of the soft palate.*

*History.*—Lief D., aged 31, was admitted to the hospital on March 6, 1916, and had recovered by March 17, 1916. On March 3, he was struck over the left side of the face by a block of wood. The left eye became swollen and was shut tight the next day; then, as the swelling here subsided, the face became swollen over the left lower jaw. He had difficulty in swallowing, and the throat felt sore. He had never had "sore throats" or any attack similar to the present one.

On admission, the chief complaint was difficult in swallowing. The temperature was 103, the pulse rate, 100, and respirations, 32.

There was a fading subconjunctival hemorrhage and ecchymosis in and under the left eye. There was no evidence of fracture of the bones of the face. The patient could barely open the mouth. The area under the left jaw was swollen, tender and firm and slightly so in the midline. The tongue was only slightly pushed up. The tonsils were normal. The uvula was the size of a man's thumb and was boggy and soft. The cervical glands were easily palpable.

*Treatment and Progress.*—An ice bag was applied to the neck and a gargle of sodium chloride was given.

On March 7, the patient swallowed with less difficulty. He could open the mouth further. The tonsils were normal. The temperature was 102.4. Induration was more marked under the midline of the jaw, and in the evening the tongue was swollen.

On March 8, about 2 a. m., the tongue was 2 inches (5 cm.) thick and was pushed tight against the roof of the mouth by the swelling beneath. Small incisions were then made in each side of the tongue, and these were enlarged by probe and hemostatic forceps. The patient was unable to swallow and was having some difficulty in breathing. After the floor of the mouth was opened, some serous fluid escaped, but no pus. After that the condition steadily improved, and during the day the temperature reached normal. Culture showed a mixed growth, chiefly of cocci.

On March 9, the tongue was nearly normal in size; dysphagia or difficulty in breathing was not present. The uvula was now about half the size that it was on admission.

On March 17, the patient had recovered and was discharged as cured.

#### SUMMARY

1. Ludwig's angina is a clinical entity, consisting of a septic cellulitis of the floor of the mouth and of the neck. Many cases usually classed under this head must be rejected.

2. Attention is called to the pathologic and clinical differences between cellulitis and lymphadenitis or lymphangitis.

3. Eighteen cases of Ludwig's angina are reported from the Episcopal Hospital, Philadelphia, with a mortality of 27.7 per cent. By contrast four cases are reported which superficially resembled but which were not really cases of Ludwig's angina.

4. The predominating rôle of dental infection as a cause is emphasized (from 65 to 83 per cent of cases).

5. Anatomic studies are reported from the Laboratory of Operative Surgery of the University of Pennsylvania, demonstrating the routes by which the infection spreads.

6. A median submental incision and an incision in one or in both submaxillary regions, extending in all cases into the cavity of the mouth, are described as valuable for drainage.

7. The cause of death usually is sepsis.

#### BIOGRAPHIC SKETCH

Wilhelm Friedrich von Ludwig (1790-1865) was the son of the parson of Uhlbach, near Stuttgart, in Württemberg. He studied medicine at the University of Tübingen, graduating in 1811. He then served his term in the army of King Friedrich of Württemberg, first as a common soldier and then as *Unterarzt* (assistant physician). He accom-

panied the army during Napoleon's invasion of Russia, reaching Smolensk. During the retreat he was taken seriously ill (typhus) at Vilna and was made a prisoner by the Russians, being carried back to Pensa, in Russia. Here he became attached, as surgeon, to the suite of a princess, and with her train went to the south of Russia, where he did many operations.

When the king of Württemberg joined the allies against Napoleon in 1814, the Württemberg prisoners were sent home from Russia. After leaving the army in 1815, Ludwig was made, by royal decree, professor of surgery and midwifery in the University of Tübingen.

In 1816, he succeeded Froriep as personal physician (*Leibmedicus*) to King Friedrich; and when the latter was succeeded by his son (King William) in 1817, Ludwig returned to Stuttgart as personal physician to the new king. Here he soon acquired a large and fashionable practice, and under a third king of Württemberg he became counsellor of the medical college, and was much occupied with administrative duties of hospitals, asylums, colleges, revision of the pharmacopeia, etc. In 1836, he was vice director; in 1842, counsellor of state (*Staatsrath*), and in 1844, director of the medical college. He retired from these duties in 1855. He had been president of the "*Württembergische ärztliche Verein*" from 1835 to 1846. He wrote little; in 1836, he described the inflammation of the neck since known by his name; and, as correctly stated by his biographer, "the short, clear, and comprehensive account which Ludwig gave of it, has been surpassed by no later description of the disease." In 1847, he published a short notice on the cure of artificial anus.

In early life he had been subject to gouty attacks; at 30 years of age he had a long illness with gastric symptoms; at the age of 50 he suffered from a severe carbuncle on the neck.

In 1861, his jubilee was fittingly celebrated. Thereafter his health broke; he developed cataract and had stone in the bladder, for which two operations (presumably lithotomy) were done. "On the seventh of December an inflammation of the neck came on, which boded the worst, and in the early morning of the fourteenth of December (1865) he lost his life suddenly, without any immediate warning."<sup>31</sup>

# TUMORS AND TUMOR-LIKE LESIONS OF THE BREAST

IN ASSOCIATION WITH PREGNANCY AND LACTATION \*

ALSON R. KILGORE, M.D.

SAN FRANCISCO

WITH A NOTE BY DR. JOSEPH COLT BLOODGOOD, M.D., BALTIMORE

## THE TREATMENT OF TUMORS OF THE BREAST DURING PREGNANCY AND LACTATION

JOSEPH COLT BLOODGOOD, M.D.

There is no question as to what the treatment should be the moment the diagnosis of tumor of the breast is made. The chief difficulty lies in making the diagnosis, especially in those cases in which the woman seeks an examination as soon as she feels a lump in the breast. Now that expectant mothers are periodically examined by obstetricians, there should be no delay.

Treatment can be briefly stated for the so-called caked breast most frequently observed in the first two weeks of lactation—noninterference. If the child does not nurse, the breast pump should be used and the nipples should be kept clean. For the acute abscess, an incision is made followed immediately by Carrel-Dakin irrigation; for the chronic abscess revealed by the character of the wall when the abscess is incised, excision of the wall beyond the inflammatory zone through the lactating breast is employed. When there are multiple acute or chronic abscesses and the signs of general infection persist in spite of multiple incisions or excisions, the entire breast should be removed to protect the patient from a serious endocarditis, myocarditis or arthritis, or even pyemia.

For the encapsulated adenoma, which will always show the gross and microscopic changes of lactation hypertrophy, excision is employed. It is my rule to let the infant nurse the breast, emptying it. The mother, of course, is prepared for the complete operation. The clinically benign tumor is resected by cutting through the surrounding breast. After the tumor is removed, it is bisected while held in the left hand of the operator, and a frozen section made. If it proves to be benign, the wound should be closed just as after the excision of an identical benign tumor in a nonlactating breast. The divided breast tissue should be brought

---

\* Submitted for publication, July 1, 1928.

\* Read before the Section on Surgery at the Seventy-Ninth Annual Session of the American Medical Association, Minneapolis, June 13, 1928.

\* This study was undertaken at the suggestion of Dr. Joseph Colt Bloodgood and is based on the records and material in his laboratory at the Johns Hopkins Hospital. End-results were brought up to date in March, 1926.

together with 00 chromic catgut after all hemorrhage is checked. Silk should never be buried in the breast tissue. The subcutaneous fat should be approximated with similar catgut, and the skin brought together with interrupted fine black silk. The wound should be dressed daily with sterile gauze. A leakage of milk will probably occur for some days. I have had experience with the excision of benign adenomas in all stages of pregnancy and lactation, and there has been no difficulty, except in making the differential diagnosis.

If the exposed tumor proves to be a cyst filled with milk (galactocoele), it should be excised with the same margin of breast tissue as for the adenoma, and the wound should be closed in the same way. If the dilated ducts leading to the nipple containing milk are cut through, no attention should be paid to them, the wound will heal just as well.

When the exposed palpable area is not a galactocoele or encapsulated adenoma, the condition may be chronic lactation mastitis without abscess, tuberculosis without caseation or abscess, or cancer. If interpretation of the frozen sections made at the operation shows that the condition is distinctly benign, it is not necessary to excise completely the infiltrated tissue of the mastitis, nor is it necessary to remove the breast. If the sections show that the condition is doubtful or malignant, complete operation for cancer should be done.

The operator will find that during pregnancy and lactation the breast tissue itself and the tissue of the margin of the breast will be much more vascular than those of a woman at the same age and of the same degree of physical development. For this reason, the operation must proceed slowly, and every bleeding point must be clamped and ligated, even when the complete operation is performed because of malignancy. The operator is called on to deal patiently with the very vascular tissue, except in the axilla. Here there is little difference.

The operative technic on the breast during pregnancy or lactation may be summed up in a few sentences:

The patient is prepared for anesthesia and the operation in the same way that any other woman is prepared for the same procedure.

The breast is emptied by nursing or by a milk pump just before operation.

One must remember to deal properly with the increased vascularity.

If the patient is lactating when the benign lesion is excised with the proper margin, there will be leakage of milk from the closed wound or the drain wound when the chronic abscess is excised. This means daily dressings with every aseptic and antiseptic precaution against infection.

These patients are good operative risks; I have never observed mis-carriage after an operation during pregnancy. If the lesion is benign and nontuberculous, and if the infected area is completely removed, the

child may continue to nurse without danger; as a rule, if the patient is properly handled, lactation will proceed unaffected. When multiple acute or chronic abscesses are present, the child should be weaned. Even in those cases in which the breast or breasts are saved, marked atrophy will follow. However, in my experience, both breasts, whether affected or not, will function during the next pregnancy, and there may be repeated normal lactations after properly treated multiple abscesses of one or both breasts. I have also observed a tuberculous breast that had healed spontaneously function at the next pregnancy, producing milk not injurious to the infant.

The most important part of any treatment of lesions of the breast during pregnancy or lactation is promptness of action. This is especially true in pyogenic or tuberculous mastitis and malignant tumors. When the benign adenoma is growing rapidly or the galactocele is getting larger, nothing is gained by delay.

In view of the fact that anxiety and worry interfere with the function of lactation, these patients must be handled in the most tactful and optimistic manner. The possibility of malignant disease or the possibility of complete removal of the breast should never be mentioned.

#### DIAGNOSIS

The factors that have increased inoperability and decreased the permanent cure in cases of cancer of the breast during pregnancy and lactation are the frequency of mastitis and galactocele and so-called "caked" breast. When the lump or induration is first felt by the patient, tradition suggests some trouble with lactation, so frequent in animals during this period, and many physicians naturally think of mastitis first.

This contribution by Kilgore will be most helpful in the control of cancer during these periods by the dissemination of the correct information that cancer does occur in the breast during pregnancy and lactation, and that if it is recognized and proper treatment given, the prognosis is fairly good, even when the lump is of some months' duration.

I shall discuss this point again and bring out the fact that although some patients are cured by the complete operation in lesions of a few months' duration, many lose their lives through metastasis during this interval of delay.

I shall review briefly some of the facts that are recorded in the histories which Dr. Kilgore studied in the surgical pathological laboratory of the Johns Hopkins University and Hospital. They date back to 1889, and I can recollect all the cases of tumors of the breast since 1893 that exhibited difficulties, because in teaching students about them each year, this group has been constantly restudied.

*Acute Abscess.*—This condition, most frequently observed during the first two months of lactation, in the beginning, was diagnosed clinically,

and the abscess was incised and drained without pathologic study. Then there was a period when the operator excised a piece of the wall of the abscess in pyogenic lactation mastitis and sent it to the laboratory, where it was examined by a pathologist who probably had never seen such a section, and the operator was astonished to receive a report of malignant disease. In one year, more than five such cases were referred to the laboratory for decision. Fortunately, in four the breast could be saved; in one the complete operation had already been performed. This rarely happens today, because physicians and nurses are better educated in the care of the nipples, and the expectant and nursing mother is properly instructed. Since 1920, the percentage of abscesses of the breast in the history of patients coming to the clinic with lesions of the breast has been reduced from more than 20 to less than 1. Rarely is there an opportunity to study microscopically the wall of an acute abscess of the breast.

*Chronic Abscess.*—In 1896, I assisted Dr. Finney in the exploration of a large cystic tumor of the right breast. The woman was nursing an infant, aged 4 months, at both breasts. The swelling had appeared a few weeks previously without fever or signs of acute abscess. When it was incised, its contents were not bloody or thick, grumous material such as one finds in cancer cysts, nor was the fluid like milk in a galactocoele or that of tuberculous or pyogenic pus, but was cloudy. We did not take cultures or make smears. Probably we would have found polymorphonuclear leukocytes and pyogenic cocci. The condition impressed us as being a chronic abscess. In cutting out the thin zone of inflammatory tissue, we cut through breast tissue filled with milk. Within a few days, the pathologist of the hospital sent in a report of adenocarcinoma, and Dr. Halsted performed the complete operation for cancer. The glands, however, showed no metastasis, and the patient is free from disease today. One must remember that there is a cancer cyst, and a cancer cyst differs from a chronic abscess of the breast by the character of its contents. In the fresh frozen section, pathologists should learn to differentiate between the chronic abscess and the cancer cyst. One of the cases in which Kilgore reported a cure was that of a patient with a cancer cyst. But chronic, like acute, abscesses are becoming rare. Nevertheless, one must learn to differentiate chronic lactation mastitis in the wall of an abscess from cancer. Many breasts have been unnecessarily sacrificed because of the inability of pathologists to make the differential diagnosis.

*Chronic Lactation Mastitis.*—Chronic lactation mastitis may occur both during pregnancy and during lactation, but it is more frequent in the later period. It begins as an area of caked breast, the area varying in size. In the beginning, the area may be very small. The presence of

fever and leukocytosis may be overlooked at the onset. As the induration progresses, there may be retraction of the nipple, dimpling of the skin, and often enlarged palpable glands in the axilla. My associate, Dr. Cohn, is just finishing his restudy of this group. The number of cases is now larger than the number of combined acute and chronic abscesses. Chronic lactation mastitis, like tuberculous mastitis, may assume the clinical picture of a malignant condition, and in many of these cases the complete operation has been performed without exploration.

In chronic lactation mastitis, the indurated breast feels as it does when diffuse cancer is present. When the breast is explored and examined with the naked eye and cut and scraped with the knife, the condition seems almost identical with cancer, and unless one is especially trained and experienced, cancer will be diagnosed from the fresh frozen section or from the later fixed and stained section. As these patients remain well no matter how extensive the operation is, and as in the majority of clinics the condition is diagnosed as malignant, it is natural that these cases should figure in statistical studies as cured cases of cancer. This gives a wrong impression concerning the prognosis of a malignant condition during pregnancy and lactation and concerning the therapeutic value of irradiation, intravenous administration of lead and other methods of combating malignant disease of the breast. In a number of cases I have performed the complete operation for cancer after an exploratory incision guided only by the gross diagnosis. Now that the condition can be recognized microscopically, this lesion of the breast, so difficult to diagnose, is becoming to infrequent that one is seldom given an opportunity to test one's ability.

*Tuberculosis.*—In the years when the unenlightened woman delayed consulting a physician, one saw tuberculous mastitis only as an abscess or a sinus, and diagnosis was not difficult. Then these patients came under observation when they had a zone of mastitis, and the same difficulty was experienced as I have just noted in chronic lactation mastitis. First, the fresh, naked eye appearance of tuberculous mastitis was mistaken for a malignant condition, and the complete operation was performed without the study of a frozen section. Then the tubercle in the frozen section was not recognized, and only the proliferating epithelial cells of lactation and the acinus disorganized by the inflammatory process were noted. Now that tuberculous mastitis can be recognized before abscess formation or caseation, this condition of the breast has become unusual. Tuberculous mastitis presents the same clinical, gross and microscopic picture as chronic lactation mastitis. When an abscess forms, there is no difficulty in differentiating both from cancer.

*Galactocèle.*—Galactocèle may occur without lactation mastitis or abscess. When it does occur thus, it is easier to diagnose.

The palpable tumor is usually spherical, and one can elicit fluctuation. If pressure on the tumor ejects milk from the nipple, there is no indication for operation. If there are two or more palpable fluctuating tumors, with and without discharge of milk from the nipple, operation is not indicated. That is, if a galactoceles can be diagnosed clinically, it should be left alone, as the majority of these enlargements disappear spontaneously. When these tumors are explored, their contents (milk) exclude the diagnosis of a cancer cyst. In the frozen section, the lining will show proliferating, degenerating, milk-producing epithelium, and in the wall of the cyst lactation hypertrophy. Galactoceles surrounded by mastitis give the same clinical picture as chronic lactation mastitis, but when explored, the milk-containing cyst in the area of mastitis practically excludes cancer. I have never yet seen cancer and galactocoele together. Nevertheless, frozen sections should be made.

*Adenoma.*—All the adenomas that I have removed during pregnancy and lactation have been encapsulated. All of them have shown the changes present in the surrounding breast. Tissue and sections have been received from many outside surgeons and pathologists because of the diagnosis of adenocarcinoma, and in many instances, as in chronic cystic mastitis, the complete operation for cancer had been performed. I am inclined to think that if one collected from the various clinics of the world the cases of adenocarcinoma of the breast in which operations have been performed during pregnancy and lactation, it would be found that in the majority the glands showed no metastasis, and that the patients survived many years without recurrence. Kilgore has shown that the majority of cancers of the breast during pregnancy and lactation are scirrhus and medullary. As a matter of fact, comedo cancer, colloid cancer, cancer in intracystic papilloma, cancer cysts and sarcoma are rare in the breast. The difficulty in recognizing adenoma in pregnancy and lactation is the microscopic appearance. This lactating adenoma is more confusing to the pathologist than the histologic appearance of chronic cystic mastitis.

*Papillomatous Cysts.*—Papillomatous cysts rarely occur in the breast during pregnancy and lactation, but one must bear them in mind. In the first place, they will be suggested by discharge of blood from the nipple. This is no more an indication for operation than the discharge of milk. When the discharge of blood is associated with a palpable tumor and pressure on it brings blood from the nipple, the diagnosis of a papillomatous cyst is made. There is no difficulty in recognizing this tumor on gross examination. It should be excised with a good margin and bisected. The cyst wall in the base of the papilloma should be inspected carefully and a frozen section made at this point, because cancer may develop in such tumors. Unfortunately, benign intracystic

papillomas are as frequently incorrectly diagnosed cancer as the lactating adenoma or chronic lactation mastitis.

*Cancer.*—It is fast becoming known that in the earliest stages cancer has no characteristic clinical picture, nor can one distinguish by palpation the early stage of a malignant tumor from a benign lesion. On palpation, the cancerous lump may appear to be an encapsulated adenoma. The cancer cyst may fluctuate like a galactoceles. On palpation, infiltrating cancer may appear almost identical with the caked breast, the lactation mastitis or tuberculosis. One does not expect to feel a caked breast in the nonpregnant or nonlactating woman. But on palpation chronic cystic mastitis at the noncystic stage feels like a caked breast in pregnancy or lactation. These two benign lesions of the breast make it difficult to recognize cancer in the early stage, and force one to make exploratory incisions for frozen-section diagnosis. Caked breast is rarest during pregnancy and after the second month of lactation; therefore, any induration or lump felt at these periods should be explored at once. In the first few days after the birth of the child and within the first two months caked breast is not uncommon, but one should expect resolution in a few days, and there should be no delay in exploration unless there is fever and leukocytosis. Then one is justified in waiting for the appearance of an abscess or the resolution of the inflammatory process. If neither occurs in ten days, the area should be explored for frozen-section diagnosis.

*Transillumination.*—I have read the paper on transillumination by Dr. Max Cutler from the Memorial Hospital in New York, and have used this method of diagnosis frequently in the past few months. All transillumination does is to distinguish a typical cyst from a solid tumor. Solid tumors and blood cysts are dark.

I have had no opportunity to try transillumination in galactoceles or cancer cyst. In the last patient there were palpable cysts in both breasts. The right nipple had recently retracted. History and palpation suggested chronic cystic mastitis, but beneath the retracted nipple of the right breast transillumination revealed a dark area not made out in the left breast. Yet on palpation this area did not seem to be cancerous. When explored an early scirrhus cancer, less than 8 mm. in diameter, was found.

*Diagnosis of Lesions of the Breast.*—The diagnosis of lesions in the breast is becoming more difficult. The physician's sense of palpation must be improved. Transillumination must be tested out. Ultimately, every operating room in the country must provide for the making of fresh frozen sections and for some one trained to interpret them. If a differential stain between the cancerous and the noncancerous cell can be discovered, it will be very helpful in this difficult histologic differentiation.

Dr. Kilgore, in his visits to my laboratory, has always made a comprehensive study of value to the laboratory, and his publications will be of value to the readers. He brought out the fact that the chance that a woman who has cancer of one breast will develop cancer of the remaining breast if she lives five years or more, is as ten is to two. He also confirmed the studies of Trout of Roanoke, Va., that pregnancy as a rule stimulates cancerous growth, and that a woman operated on for cancer would have a better chance if there was no further pregnancy. Thus he justified roentgen sterilization, which it has been my rule to practice in those cases in which this may be properly presented.

## TUMORS AND TUMOR-LIKE LESIONS OF THE BREAST IN ASSOCIATION WITH PREGNANCY AND LACTATION

ALSON R. KILGORE, M.D.

This paper is the result of a study of the incidence and behavior of tumors and tumor-like lesions of the breast first noted by the patient in association with pregnancy or lactation. To the best of our knowledge, this is the first report of a study of a large series of cases from this point of view.<sup>1</sup>

Changes in the breast associated with the function of lactation begin early in pregnancy, and involution to the normal resting state of breast tissue is not complete until an appreciable interval of time has elapsed following the cessation of actual nursing. We are here interested in the incidence of lesions arising during functional activity, and have, therefore, included tumors arising at any period from the beginning of pregnancy to the end of, or immediately after, lactation. To simplify the discussion, tumors arising at any of these periods will be called "lactation tumors," and those arising during periods of breast inactivity, "nonlactation tumors." As we have no way of determining the exact moment of histogenesis of any neoplasm, we have been obliged to base the study on the time of first observation of the lesion by the patient.

From a total of over 1,500 cases presenting pathologic processes of the breast, we have selected those tumors first observed by the patient

---

1. The relation of function of the breast to the incidence of cancer of the breast later in life has been discussed in the surgical literature. According to various authorities, normal lactation does not predispose to cancer, and, in fact, women who have borne and nursed children are less likely to be affected with cancer of the breast in later life than are single women. Certain abnormalities of lactation may, however, predispose to cancer later. See Deaver and MacFarland: *The Breast*, Philadelphia, P. Blakiston's Son & Company, 1917, p. 523. Levin: *Studies in Cancer*, George Crocker Cancer Research Fund, 1912, vol. 2, pp. 15 and 19. Lane-Clayton, Janet E.: *A Further Report on Cancer of the Breast: Reports on Public Health and Medical Subjects*, Ministry of Health, London, no. 32, 1926.

(1) at the time of, or immediately after, miscarriage, (2) during pregnancy, (3) during lactation and (4) at the end of, or immediately after, lactation. Tabulations have been made to answer as far as possible the following questions:

1. What tumors and tumor-like lesions of the breast may arise (be first observed) in connection with pregnancy and lactation, and what

Fig. 1.—Cancer in lactating breast. Tumor observed at seventh month of pregnancy; nursed child one year; well twenty-one years after operation.

is their relative frequency as compared with that observed during inactivity of the breast?

2. Is a knowledge of the age of the patient at the time of onset helpful in making a diagnosis?

3. Is a knowledge of the stage of pregnancy or lactation at which the tumor is first observed helpful in making a diagnosis?

4. What is the prognosis of lactation tumors?

Acute lactation mastitis has not been included in this study because this condition ordinarily does not present a diagnostic problem. It either resolves or declares itself as a frankly inflammatory lesion within a few days. There is an interesting group of cases of chronic lactation mastitis, a condition presenting itself occasionally in such form as to make a differential diagnosis from cancer extremely difficult. This group has been studied in this laboratory by Dr. L. C. Cohn and is the

Fig. 2.—Encapsulated adenoma with lactation hypertrophy. Excision of tumor at seventh month of pregnancy; well five years after operation.

subject of a complete report now in preparation for publication. In the tables in this study have been included only those cases in which a lump occurred and was first noticed by the patient during pregnancy or lactation, and in which the clinical features of acute inflammatory mastitis were not present.

All the common tumors and chronic pathologic conditions of the breast were found to arise (or be first noted by the patient) in connection with mammary activity, with the exception of chronic cystic mastitis in its tumor-like forms.

Of the 1,521 lesions of the breast (not including chronic cystic mastitis and acute inflammatory mastitis) on which this study is based, 96, or approximately 6.3 per cent, were first observed by the patient in connection with pregnancy or lactation.<sup>2</sup>

Table 1 is arranged to show the actual number of instances of each lactation tumor and also what percentage of the total number of lactation tumors each type forms.

A review of table 1 indicates that in this series, of a total of ninety-six lactation tumors, eighty (or 83 per cent) were cancer, galactocele, tuberculosis or encapsulated adenoma, in the order of frequency named. At times of inactivity, chronic cystic mastitis, either with or without a single large cyst, presenting itself as a tumor in the breast, takes the

TABLE 1.—*Number and Percentage of Each Type of Lactation Tumor*

	Number Arising in Pregnancy or Lactation	Percentage of All Lactation Tumors	Number Arising at Other Times	Percentage of All Non- lactation Tumors
Cancer	49	51.0	1,053	73.7
Galactocele	13	13.5	6*	0.4
Tuberculosis	9	9.4	27	1.7
Encapsulated adenoma	9	9.4	276	19.3
Intraeystle papilloma	2	2.1	24	1.7
Cystic adenoma	0	0.0	22	1.6
Lipomas, dermoids, etc	4	4.1	22	1.6
Chronic lactation mastitis (not clinically inflammatory)	10	10.4	0	0.0
Total		96		1,425

\* The galactocele, being a milk cyst, from its nature, must arise in association with milk secretion. Some, however, are not discovered by the patient until after a considerable time following lactation, and, since this is a clinical study, only those observed by the patient during pregnancy or lactation have been included as "lactation tumors."

place of galactocele and tuberculosis, so that at other times than during functional activity, the order of frequency is cancer, chronic cystic mastitis and encapsulated adenoma.

Table 2 shows the number of cases of each type of tumor arising in breast activity compared to the total number of cases arising at all times.

It will be apparent that nearly 45 per cent of all cancers of the breast, regardless of the age of the patient, arise in connection with breast activity. Considering only those in women under the age of 47 (roughly the limit of the childbearing period), 10 per cent arise in association with pregnancy or lactation.

One feature of interest in the first two tables is the relative and actual frequency of lactation tuberculosis. Twenty-six per cent of the

<sup>2</sup> Instances of cancer arising in a breast the seat of a long-standing lump originally observed in lactation, e. g., the scar of a lactation abscess have not been counted as arising in lactation.

cases of tuberculosis of the breast (table 2) was first observed during pregnancy or lactation, comprising nearly 10 per cent of all lactation lesions (table 1). The incidence of tuberculosis in the entire series of 1,500 lesions of the breast is much higher than that indicated in the literature as collected by Deaver and MacFarland.<sup>3</sup> No explanation is obvious, and none is offered for this deviation from other experience. It occurs as probable, however, that the relatively high incidence of tuberculosis of the breast in association with lactation is due to the lighting up of latent foci by the increased circulation of functional activity.

TABLE 2.—*Tumors Arising in Breast Activity Compared with Those Arising at All Times*

	Total Arising at All Times	Lacta- tion Tumors	Percentage Arising in Lactation
Cancer .....	1,099	49	4.45
Cancer (including only cases arising under 47 years—childbearing period) .....	493	49	10.00

Intracystic papilloma.....	0	1	0	0	1	0
Lipomas, etc. ....	0	1	0	1	2	0
Chronic lactation mastitis.....	1	1	5	2	1	0

From table 3 it will be plain that only the most general deductions can be drawn from the age at which a lactation tumor arises. Cancer in lactation, as at other times, is extremely rare in women under 25—no cases are recorded in this series—while benign lesions are rare in women over 40 years of age; one intracystic papilloma, two nonindigenous tumors (lipomas, dermoids, etc.) and one chronic lactation mastitis are found in this series. More than 90 per cent of the cancers arose in women above the age of 30, while nearly 70 per cent of benign conditions arose in women under 30; so that, as a broad generalization, it may be said that tumors of the breast in functional activity in patients

3. Deaver and MacFarland (footnote 1, first reference).

under 30 are more likely to be benign, and in patients over 30 are more likely to be malignant. In this series, all lesions first observed in lactation in women beyond the age of 45 were cancer.

#### PERIOD OF PREGNANCY OR LACTATION

The stage of pregnancy or lactation at which the tumor is first observed is of even less assistance in diagnosis. All varieties of tumor may be observed by the patient at any stage (table 4).

Fig. 3.—Encapsulated adenoma with lactation hypertrophy. Excision of tumor at seventh month of pregnancy; well five years after operation.

The one fact of importance brought out by table 4 is that the period of pregnancy or lactation at which the tumor is first observed is of no help in diagnosis, especially in cancer. Most swellings of the breast arising early in lactation are either caked breast or inflammatory mastitis; yet 25 per cent of all lactation cancers in this series were first discovered in the early months of lactation—a considerable number during the first four weeks (see note under table 4). It is, therefore,

not safe to delay the exploration of a lump early in lactation on the assumption that it is inflammatory. This mistake is not uncommon if one may judge from the reports of lactation cancer in the literature; the delay is not measured by days or even weeks, but by months.

#### PROGNOSIS OF LACTATION TUMORS

Cancer of the breast during pregnancy and lactation has been commonly regarded as almost uniformly fatal. It has been a matter of no small interest, therefore, to note a considerable number of cases in this series in which cure was obtained.

Of the forty-nine lactation cancers herewith reported, end-results are known in forty-six. Eight of the patients (all with definite medullary or scirrhus cancer) were well four and one-half, eight, eight,

\* Of the twelve cancers arising during the first four months of lactation, seven were observed before the end of the first month, nine before the end of the second month.

ten, thirteen, eighteen, twenty and twenty-one years, respectively, after operation. As experience with cancer goes, this indicates a far from hopeless prognosis for cancer of the breast associated with lactation activity.

For purposes of comparison with other groups of cancer of the breast, the cases have been classified according to involvement or absence of involvement of axillary glands at the time of operation, with the following results:

In seven cases without involvement of the axillary glands, five patients, or 70 per cent, were cured; in twenty-six cases with involvement of the axillary glands, 3 patients, or 11.5 per cent, were cured.

It is also interesting to note that these good results were not entirely due to the best surgical measures. Only two patients were subjected to operation immediately on discovery of a tumor. The delay in the remaining six varied from three months to over a year. The patient who was alive and well twenty-one years after operation noticed a lump in

the seventh month of pregnancy, nursed her baby for a year, and was then operated on.

#### REPORT OF CASES

The histories of the eight cases in which cure was obtained present points of sufficient interest to justify inclusion of abstracts in this report:

CASE 1—A woman, aged 45, with scirrhus cancer, first noticed a tumor four months before operation and two months before cessation of lactation. Complete one-stage operation for cancer was performed. The lower axillary gland was involved. At the last report, the patient was well four and a half years after operation.

Fig. 4—Encapsulated adenoma, first observed during lactation seven years before operation. Excision of tumor only; frozen section diagnosis: probable adenocarcinoma

CASE 2—A woman, aged 38, with scirrhus cancer, noticed a lump when she had just ceased nursing. At operation, a tumor with a cystic cavity was found, in the wall of which microscopic examination showed cancer. Four days later, the remainder of the breast and the axillary glands were removed. Cancer was found in the remaining breast tissue, and a small but typical metastasis in a low axillary gland. The patient was well twenty years after operation.

CASE 3—A woman, aged 38, with scirrhus cancer, first observed a tumor at cessation of lactation, one year before operation. Only the tumor was excised. Microscopic examination showed cancer, and the complete breast and axilla opera-

tion was done two days later. Axillary metastasis was not found. The patient was well eight years after operation.

CASE 4.—A woman, age 42, with medullary cancer, first observed a tumor two months before the birth of her child fourteen months before operation. There was a history of mastitis and abscess in this breast nineteen years previously, and the breast had not been used for nursing since, but the child, now 1 year old, was still nursing from the opposite breast. The cancerous breast showed typical areas of lactation hypertrophy under the microscope. Complete one-stage operation for cancer was performed. Axillary metastasis was not found. The patient was well twenty-one years after operation.

CASE 5.—A woman, aged 39, with medullary cancer, first discovered a tumor eight months before operation while nursing her child. She continued to nurse with both breasts until three weeks before operation, though with pain and less milk in the affected breast for the last five months of this time. Complete one-stage operation was performed. She was well eighteen years after operation.

CASE 6.—A woman, aged 33, with a medullary cancer, noticed a small lump the size of buck-shot in the breast after the birth of her first child, four years before

Fig. 5.—Tuberculosis of the breast in a patient, aged 28. First observed in fourth month of pregnancy; rapid growth; operation one month after discovery of tumor; retraction of nipple and slight fixation of skin. Gross appearance at exploration suggested cancer; radical operation; well eleven years after operation.

operation, but it did not give her any trouble. She forgot about it until the second child was born five months before operation, when the lump began to grow. Complete one-stage operation was performed. Axillary metastasis was not found. She was well thirteen years after operation. One year after operation, her physician reported that she was pregnant again.

CASE 7.—A woman, aged 43, with a medullary cancer, noted a tumor at the end of lactation, one month before operation. The child was eleven months old. The clinical diagnosis was benign. Exploration was followed by immediate complete operation. Axillary metastasis was not found. She was well eight years after operation.

CASE 8.—A woman, aged 33, with scirrhus cancer, immediately after childbirth and twenty months before operation, had a lump appear in each breast. Both breasts were tender. The lump in the right breast disappeared, but the one in the left breast remained, the tenderness disappearing. The child nursed from both breasts about fourteen months. One month before cessation of lactation, the tumor

in the left breast was removed. Three months later, a lump returned at this site. Examination seven months after the first operation, showed two lumps in the left breast, to one of which there was beginning skin adherence with fat atrophy.

Complete one-stage operation was performed. The axillary glands were involved. She was well ten years after operation and had nursed three children from the remaining breast without trouble.

The end-results in five of the nine cases of lactation tuberculosis are known. One patient died six years after operation, death following

Fig. 6.—Same case as figure 5. Microscopic appearance.

an operation for ovarian trouble. One patient, at the end of nine years, had borne and nursed five more children, using the remaining breast without difficulty. Three other patients were well from nine to ten years after operation.

End-results following removal of galactoceles, adenoma and other benign lesions arising during lactation were not found to differ from the end-results for the same lesions occurring during inactivity of the breast.

## SUMMARY

1. Ninety-six (over 6 per cent) of 1,521 tumors of the breast of all kinds (except chronic cystic mastitis and acute inflammations) arose during, or shortly after, pregnancy or lactation.

2. Of all cancers of the breast, 4.5 per cent arose in association with breast activity and 10 per cent in women under the age of 47.

3. Cancer, galactocoele and tuberculosis and encapsulated adenoma comprised, in the order named, 83 per cent of all lactation tumors. During breast inactivity, the order of frequency was cancer, chronic cystic mastitis and encapsulated adenoma.

4. The age of the patient at the time of onset of lactation tumor is of but little help in diagnosis. In general, over 90 per cent of cancers arose in women over 30 years of age and nearly 70 per cent of benign lesions, in women under 30.

5. The stage of pregnancy or lactation at which a tumor is first observed is of little significance. Cancer arises as frequently in the early months and even in the early weeks of lactation when mastitis is common and confusing, as at any other stage.

6. The prognosis of cancer in connection with pregnancy and lactation is anything but hopeless. Seventeen per cent of unselected patients traced were well from four and one-half to twenty-one years after operation. Five of seven patients without axillary metastases at the time of operation were among the groups of patients who were reported well.

7. The prognosis of tuberculosis of the breast arising during lactation, as far as shown by the end-results in this small series, is good.

## CLINICAL SIGNIFICANCE OF THIS STUDY

The pregnant and lactating woman should be watched with care. Cancer may arise at any stage of pregnancy or lactation, and the patient, as well as her physician, may be easily misled by the frequency of inflammatory lumps during nursing. The prognosis of cancer in connection with lactation is far from hopeless, and the benefit of immediate, complete operation should be given in each case. No lump arising during lactation should be subjected to prolonged delay before exploration on the assumption that it is inflammatory.

## ABSTRACT OF DISCUSSION

DR. WILLIAM C. MACCARTY, Rochester, Minn.: I cannot disagree with Dr. Kilgore about anything he said. His results with carcinomatous lactating breasts, are, of course, extremely unusual. There are styles in surgery just as there are styles in other things. Fifteen or twenty years ago, programs were filled with papers discussing carcinoma of the breast, chronic cystic mastitis, etc. There

has been a lull in the last five or ten years, and I think that is largely due to the excellent standardization of technique and the general recognition of the fact that all cancers and many tumors which are not cancerous should be removed. I have been interested in studying our series of cases of conditions of the breast over the twenty-year period. In the twenty years one can see definite changes taking place in the material. It began to change about ten years ago. Difficulties in clinical diagnosis were increased. That was due to the cancer campaign being carried on so extensively. People were advised to come for diagnosis with their sores and lumps when they were small, and were promised that if they were small enough the condition might be cured. As a result of this extensive campaign over the country, certain things have happened, especially in mammary conditions. Several years ago I reported on a series of 1,800 conditions of the breasts, 15.2 per cent of which did not have absolutely positive textbook signs and symptoms of being either benign or malignant. A few years after that I studied another series of 300 cases with the same thought in mind of finding whether the difficulties were increasing or not. In that series, 7.7 per cent had doubtful preoperative diagnoses, which meant that these breasts must be studied with biopsy before the diagnosis could be made.

Again, a few years after that, I studied a series of 525 breasts in the same fashion. The diagnosis was doubtful in 37.4 per cent and a biopsy was necessary before a definite diagnosis could be made. That means that difficulties have increased because patients are coming to us with smaller lesions, lesions which do not present the classical signs and symptoms as they are seen in the textbooks. Just before I left home I looked up the last 165 cases of cancers of the breast to see what had happened. Twenty-three per cent, with and without glandular involvement, came to operation and the diagnosis was made by biopsy; in other words, these cases did not have the classical signs and symptoms of cancer, which, of course, increases our difficulty. If this whole series were totaled, one may safely say, I think, that 25 per cent of all mammary conditions do not present the classical signs and symptoms, and therefore difficulties of clinical diagnosis are increasing. I imagine they will continue to increase. Something must be done in order to take care of these cases, and I believe (and this is the practice which has been carried on for twenty years), that all tumors of the breast which do not have the classical signs of cancer as per textbooks, must be removed, provided, of course, the patient can stand the operation. In those cases with classical signs a radical operation may be performed immediately, but there are many cases without classical signs from which specimens must be removed for diagnosis. We never advise incision of a tumor of the breast. Remember that if a biopsy is to be done, the tumor must be excised widely, and in some instances the whole gland-bearing areas removed and the tissue submitted for examination. The cases Dr. Sistrunk and I studied ten or twelve years ago were studied relative to the time at which the breast was removed after the biopsy was made. We found then, that if the biopsy is made at the time of the second or complete operation, there are no changes in postoperative results, but if we wait two or three weeks after making the initial biopsy before doing the second operation, then our statistics are not so good.

DR. ALSON KILGORE: We were just as much surprised as Dr. MacCarty over the end-results of our cases of cancer of the breast occurring during lactation, but I went over the slides carefully in each of these cases, and none of them was of the borderline malignant group, the adenocarcinomas, all of them were true scirrhus or medullary cancers. Nor were the good results due to early and proper surgical measures in most of the cases. The delay between the observation of the lump and operation was measured not usually by days or weeks, but

actually by months and in some cases ran to over a year, and in most of the cases during this period of delay there was a longer or shorter continuance of lactation. The explanation of the success in certain cases may be found in the grading of the growths. The principles of the grading of cancer was first introduced by Dr. Broders, who is Dr. MacCarty's associate, working first with epitheliomas. Some years ago Dr. Greenough carried this principle to the grading of tumors of the breast, and in his hands the figures were certainly conclusive. Perhaps I am not thoroughly familiar with the grading of tumors through Dr. Greenough's microscope, but I have just come from restudy of this group in an attempt to grade them according to Dr. Greenough's scheme, and have been unable to make our cases fit as they should.

DR. S. W. HARRINGTON, Rochester, Minn.: I wish to thank Dr. MacCarty for stressing the point in regard to the frequency in which malignancy of the breast cannot be diagnosed by physical and clinical observations and the advisability of wide excision of these tumors for microscopic examination. I believe that the operative results for malignancy of the breast can be improved very markedly if more of these doubtful cases are treated in this way, and if malignancy is found, brought to early radical amputation. In those cases which come to operation with extensive growths and glandular metastasis, the most radical operation usually produces only a palliative result.

# PERIOSTEAL LYMPHATICS \*

ELDRIDGE CAMPBELL, M.D.

Louise Bowles Fellows, Children's Hospital School

BALTIMORE

Little or nothing is known concerning the lymph supply of the marrow and cortex of bone. As early as 1875, Karl Langer found lymphatics in the periosteum, but even this phase of the subject has received little attention. If there be a definite lymphatic system draining bone, then it probably plays a rôle of some importance from a pathologic as well as from a physiologic standpoint. At the suggestion of Dr. William S. Baer, a study of the subject was undertaken. The following report includes the work done thus far, which is preliminary in nature.

## REVIEW OF THE LITERATURE

Following Langer's <sup>1</sup> pioneer work, Budge <sup>2</sup> and Schwalbe <sup>3</sup> succeeded in injecting periosteal lymphatics and gave detailed descriptions of their coursing into the cortex. They pictured a network of lymph vessels in the outer layer of the periosteum connecting with a system of endothelial lined lymph spaces underneath the cambium layer. Dye injected into these spaces was said to spread both out into the periosteum and back into the cortex; in the former direction by ordinary lymph vessels, but into the bone by an endothelial lined lymph space. Through the latter ran a blood vessel. Neither the identity of these vessels nor the proof of their arrangement is clear. Rauber <sup>4</sup> also pictured an endothelial lined lymph space in the haversian canals through which ran both the artery and vein. Klein <sup>5</sup> identified lymph vessels in the haversian canals, and Cruikshank <sup>6</sup> is said to have traced them from the periosteum into the cortex.

Concerning the marrow cavity itself, Rogers and Josue <sup>7</sup> and others, have held strongly to the view that lymphatics are not present. On

the contrary, Kolodny<sup>8</sup> injected India ink into the femoral marrow cavities of a number of living animals, and at a later date traced the dye throughout the length of the bone. It coursed through two channels, where it emerged in the anterior intertrochanteric line in a well defined

Fig. 1.—Costochondral junction of a kitten; india ink injected into periosteum, cleared by Spalteholz method. canal. Continuing his search, he found the dye in the inguinal lymph nodes. This, he concluded, proved the presence of lymphatics in the

marrow cavity. The correctness of this work has been questioned by Piney,<sup>9</sup> who drew attention to the fact that the experiments were not well controlled and that this intertrochanteric lymph channel might, in reality, have been a vein.

Before attempting to probe the question of lymph vessels in the marrow or cortex, it seemed necessary definitely to establish the fact that such channels really exist in the periosteum, and if so, to learn

Fig 2—Costochondral junction of a kitten, showing two areas of periosteal lymph plexus, filled from an injection on opposite side of bone. *V* indicates the vein

something of their arrangement. As already mentioned, several other authors have stated that lymph vessels do exist in the periosteum, but have gone on to describe their entrance into and passage through the cortex in such a manner as to leave some doubt in one's mind whether they were dealing with real lymph vessels or simply with small blood vessels and tissue spaces. For example, Budge and Schwalbe described

<sup>9</sup> Piney, A : The Relation of the Bone Marrow to the Sympathic System, *Arch Surg.* 13:615 (Oct) 1926

a single concentric blood vessel with a surrounding lymphatic in a tiny haversian canal. Is it not possible that such a configuration was only a blood vessel within tissue space? Likewise the demonstration of subperiosteal lymph spaces is hardly convincing. Might not such injected areas be simply extravasations of dye where the periosteum is loosely attached? It is to be recalled that such lymph spaces were for a long time thought to exist in connective tissue, until MacCallum<sup>10</sup>

Fig. 3—Costochondral junction of a human infant. A glass cannula was inserted twice through the cut in the periosteum. The plexus is rather deep as in figure 4.

demonstrated that they simply marked the spot where a lymph vessel had ruptured on injection and dye had been forced into the tissues.

#### MATERIAL AND METHOD

The first attempt to inject lymphatics around bone was to force a back flow of dye from the thoracic duct. Advantage was taken of the fact that lymphatic valves are not developed in embryonic pig under from 5 to 6 cm. in length.

<sup>10</sup> MacCallum, W. G.: *Bull. Johns Hopkins Hosp.* 14:1, 1903.

In a considerable number of such animals, india ink was injected through a fine glass cannula into the thoracic duct. Although the thoracic and abdominal plexuses filled well, dye could not be traced back to bone. Direct injection of the dye into, above and beneath the periosteum in embryo pigs of about 10 cm. in length was also tried, without much success.

Finally, a human infant who had died in delivery was obtained. With the tissues kept warm, it was found that india ink injected slowly into the outer

Fig. 4.—Costochondral junction of a human infant. The lymph plexus in perichondrium is injected.

layer of periosteum, under low pressure, would frequently give a clearcut lymphatic spread. The ribs, especially the costochondral junctions were most readily accessible, and in these experiments, gave the best results. Cats, kittens, dogs, rabbits and human infants similar to the one already mentioned were used. The younger animals proved more satisfactory.

India ink diluted with an equal amount of water served as the dye. For the injection, glass cannulas, with points drawn out so fine that the dye could barely be blown through, were used. The shaft of the cannulas was bent about 90 degrees and a small piece of soft rubber tubing attached for a mouth

piece. With these conveniences the point could be guided, and the pressure of injection kept to a minimum. The specimens were cleared by the Spalteholz method.

Before describing some of the injections, it is well to recall certain characteristics of small lymphatics in general. Besides the thinness and delicacy of their endothelial lined walls, one of the more striking features is their irregularity. This lack of uniformity applies not

Fig. 5.—Section through the epiphyseal line (rib) of a kitten. *L* indicates large lymph vessel associated with smaller similarly injected vessels nearer the epiphyseal line; *B*, unfilled blood vessel, *P*, periosteum cut tangentially.

only to the frequently varying caliber of the individual vessel but also to its path and numerous communications within the plexus. The topographic result is a rather characteristic "lymph pattern," which is different from that of a blood vascular pattern. Similarly, the valvular beading of larger lymphatics, as well as the relative thinness of their walls, makes them readily distinguishable from the blood vessels which they accompany. With this in mind, a study of these injections

convinces one that a definite plexus exists in the periosteum. Briefly, the following points were noted: In the outer layer of periosteum and perichondrium of the costochondral junctions, there is a rich plexus of lymphatics. It is particularly intricate in the younger animals. This plexus, when injected, is different in both "pattern" and minute appearance from a blood vascular plexus (fig. 1, 2, 3 and 4). It consists of many small, thin-walled, freely communicating vessels, irregular both in size and course. They drain into larger valvular vessels, which are to be seen, as in figure 1, accompanying the blood vessels.

One interesting feature was the apparent lack of valves within the plexus. There is, of course, great variation in the caliber, but nowhere among the smaller vessels could a valve definitely be made out. This, apparently, is not uncommon in parenchymatous organs, such as the ovary and liver. Perhaps this point, if true, is of some clinical significance, as, for example in the spread of the osteomyelitic infection.

The second point of note was the extent or communication of the plexus inwardly, i. e., into the bone. By serial section, vessels could be traced down into and even through the cambium layer, but they could not be followed into the cortex, as Langer, Budge and Schwalbe claimed was done by them. With injections in blood vessels, however, this was readily seen. At the epiphyseal line, however, a crossing and a deeper penetration seems to obtain. Figure 5 shows a section of this region following the injection of the adjacent periosteal lymphatics. In this instance, there was a definite "lymph pattern" filling in the periosteum and no blood vessels were seen to be injected. The section shows a thin-walled, irregular vessel "*L*" alongside which lies an unfilled blood vessel "*B*." Associated with "*L*" are similar vessels nearer the line of ossification. Considering the character of the vessel, the injection of the overlying lymph plexus in the periosteum, and the nearby unfilled blood vessels, it is highly indicative that these injected vessels are lymphatics. Perhaps they are only veins, but they differ markedly from those blood vessels, which for sake of comparison, were purposely injected.

#### SUMMARY

1. A definite lymph plexus was found in the periosteum and perichondrium at the costochondral junctions in certain animals.
2. This plexus exists largely in the outer layer of periosteum.
3. The plexus is drained by valvular vessels accompanying the blood vessels.

4. Within the plexus there are few, if any valves, the vessels being freely communicating.

5. Lymphatics are thought to have been traced down to the epiphyseal line.

6. Lymph vessels could not surely be traced from the periosteum into the cortex in this material.

# CARCINOMA OF THE HAND\*

MICHAEL L. MASON, M.D.

CHICAGO

Carcinoma of the hand forms an interesting chapter in the study of the surgical treatment of the upper extremity. The incidence of neoplasms of the hand is not great, though of the malignant ones carcinoma is by far the most frequent and important. Despite the fact that injury, chronic infections and scars play important etiologic rôles in the development of nearly 40 per cent of carcinomas of the hand (exclusive of roentgen carcinoma), scarcely 10 per cent of cutaneous carcinoma occurs in this location. Winiwarter<sup>1</sup> found only nine instances of carcinoma of the extremities among 548 cases of cancer. Gurlt<sup>2</sup> collected a series of 3,422 reported instances of carcinoma, and of these 1,160 were of the face and only 155 were located on the extremities. Heimann,<sup>3</sup> in a much larger series of 20,544, reported but 207 on the extremities, 124 on the lower and eighty-three on the upper. Of the latter, fifty-three were on the hand and fingers and thirty on the arm and forearm. Würz<sup>4</sup> noted four carcinomas of the hand among 502 cancers of the skin; and Bulkley and Janeway<sup>5</sup> reported only two from 417 carcinomas of the skin. Table 1 shows the incidence of cases of carcinoma of the hand among all patients with carcinoma entering the surgical services of Wesley Hospital during a period of fifteen and a half years. It does not include cases on medical or dermatologic services. From it one sees that scarcely 10 per cent affected the skin, and slightly more than 1 per cent the upper extremity.

According to Labiche,<sup>6</sup> the first specific mention of carcinoma of the hand was made by Behrends<sup>7</sup> in 1827. Marjolin and Blandin, Stein-

hausen and Jabert de Lamballe<sup>8</sup> should also be included among the early commentators. Rudolph Volkmann<sup>9</sup> collected and reported from numerous sources 223 cases of carcinoma of the extremities. In his thorough and painstaking study he divided the cases into three main groups or divisions: In one group he placed the blastomas developing on the basis of some previous irritation, infection, scar or trauma; in a second group those developing from some previous neoplasm, and in a third group those coming on the normal skin. Several subsidiary groups made necessary by paucity of data or special clinical features were added. Eighty-nine of his series were located on the upper extremity; of these, fifty-six were on the dorsum of the hand, thirty-two on the arm and forearm and one on the palm. Volkmann gave a good prognosis for all except the ones developing from some previous neoplasm.

During the next year, Michael<sup>10</sup> reported twenty-six proved cases of carcinoma of the extremities from the Tübingen Clinic and, adding four-

teen instances reported by Schneider (from von Bergmann's clinic), brought up the total to 263; 105 of these were on the upper extremity (sixty-four on the dorsum of the hand, twenty on the forearm, seventeen on the arm and three in the palm). He conceded them a good prognosis as did Volkmann.

Astié's<sup>11</sup> excellent thesis has been overlooked by many who have written on carcinoma of the hand. His study was confined to epitheliomas, of which he reported ten cases, all on the dorsum. He followed Volkmann's classification and agreed with Reboul<sup>12</sup> that the more malignant tumors developed from previously existing neoplasms.

8. Marjolin and Blandin, 1829; Steinhausen, 1837, and Jabert de Lamballe, 1843, quoted by Labiche: *L'épithélioma de la main*, Thèse de Paris, 1897.

12. Reboul, J.: *Épithélioma du dos de la main. Propagation aux vaisseaux et aux nerfs*, Arch. prov. de chir. 2:114, 1893.

He did not belittle the condition but advised early operative treatment, and in cases gone too far to give any hope of a cure, favored palliative operations because of the relief they afforded.

Labiche<sup>6</sup> wrote his doctorate thesis on epithelioma of the hand. He, in common with Astié,<sup>11</sup> was not inclined to minimize the gravity of the condition despite its long and slow course. He noted that metastases may occur without involvement of the local lymph glands.

Franze<sup>13</sup> reported twenty-one cases of carcinoma of the extremities from the von Hacker Clinic, observed during the previous twenty years. The condition in seven of these was on the upper extremity. He noted involvement of local lymph glands in twelve cases (57 per cent), and gave some interesting figures on the prognosis of the condition, showing 69.7 per cent cures and 30.29 per cent failures, exclusive of the carcinomas arising from some previous neoplasm.

Couëdic<sup>14</sup> concluded that these epitheliomas developed from the interpapillary parts of the malpighian layer. The tendency to spontaneous cure was noted, and he quoted Besnier and Doyen, who said that new foci of carcinoma usually sprang up along the border despite central epithelization. Couëdic advised strongly against the common practice of his day—cauterization.

Von Brunn<sup>15</sup> made the last great collection of carcinomas of the extremities. His report covers 368 carcinomas, 140 (38 per cent) of which were on the hand. His elaborate statistical tables were carefully compiled, and from his study he could find only 35 per cent of definite cures. A number of his patients presented multiple carcinomas, i.e., on both legs, both hands, leg and lip, hand and lip, leg and breast, etc. He showed that conservative measures properly carried out resulted in as many cures as did radical operations.

Peraldi<sup>16</sup> considered the prognosis fairly grave, though the type of lesion and age of the patient affected it. The cauliflower type of carcinoma and those occurring in young people were by far the most malignant.

Fox<sup>17</sup> studied the question thoroughly and made the pertinent observation that the rarity of occurrence of carcinoma on the palm threw doubt on the rôle of trauma in the etiology and pointed to some

differences between the type of skin on the palm and that on the dorsum which fact probably determined the localization of the lesion.

Cumston<sup>18</sup> wrote an interesting and scholarly account of the condition. He assumed a radical attitude in regard to treatment.

The history of the knowledge of roentgen dermatitis and carcinoma dates back to Ouidin (1897), who recognized the condition scarcely two years after the notable discovery of Roentgen in 1895. Since the time of Ouidin, a good deal has been written on this subject, and considerably more than a hundred cases of carcinoma of the hand resulting from injury from the roentgen rays have been reported. The medical profession has an especial interest in roentgen carcinoma, as it is the physician and seldom the patient who suffers and as it is the constant chronic adventitious exposure incident to the application of the ray and not the burn which occasionally results that appears to give rise to the dermatitis and its subsequent malignant changes. The medical profession is particularly indebted to Dr. Charles A. Porter of Boston for his early interest and study of these lesions. In 1907, in collaboration with Charles J. White, who carefully studied the histology of some thirty sections, Porter<sup>19</sup> called the attention of the medical profession to the "great danger of all persistent x-ray ulcerations and especially to those which have followed with a few years' interval the chronic skin lesions of the earliest operators." In Cole's<sup>20</sup> excellent paper may be found an historical review to which the reader is referred.

This paper is based on: (1) Twenty-five cases of carcinoma, precarcinomatous ulcers and roentgen dermatitis. The majority have been patients of Dr. Allen B. Kanavel; the others have been observed by numerous physicians to whom I am indebted for the privilege of reporting. Eight of the twenty-five cases were roentgen dermatitis with carcinoma, two were roentgen dermatitis without carcinoma, one was a radium wart of the thumb, seven were carcinomas following trauma or scarring of the hand, one was a precarcinomatous ulcer from an alkali burn, one was a carcinoma developing from a wart, two were carcinomas developing from the previously unchanged skin, and three were carcinomas in which the history was faulty and no conclusions as to etiology could be made. (2) The collection from the literature of 241 reported cases of carcinoma of the hand exclusive of roentgen and radium carcinoma and dermatitis. (3) The study of the literature on roentgen and radium dermatitis.

20. Cole, H. N.: Chronic Roentgen-Ray Dermatoses as Seen in the Professional Man, *J. A. M. A.* **84**:865 (March 21) 1925.

In reporting the twenty-five cases which form the basis of this report I have followed von Volkmann's scheme in the main with the exception that Volkmann's original first group has been divided into two subgroups. Thus, Volkmann classified carcinoma of the hand into four main groups: (A) Those arising as the result of some trauma or irritation or on the basis of a scar; (B) those arising from a previously present growth, such as a wart, or nevus—this group may be subsequently divided into B', those in which the new growth has been congenital, and B'', those in which the growth (usually a wart) has appeared later in life; (C) carcinomas arising de novo from the previously unchanged skin, and (D) a group which is made up of all those cases in which the data are too meager to allow classification. In my report I have purposely considered separately the irradiation carcinomas (group A 1) as they form so large and distinct a group.

#### GROUP A 1: ROENTGEN AND RADIUM DERMATITIS AND CARCINOMA OF THE HAND

##### CARCINOMA

CASE 1.—Dr. —, Wesley Memorial Hospital, service of Dr. Kanavel, began working with the roentgen ray in about 1903. In 1904 or 1905 he developed a dermatitis on the dorsum of the left hand, particularly marked on the index finger. On the advice of a surgical consultant, the index finger was amputated at the proximal interphalangeal joint, and somewhat later, presumably because of further changes, amputation was performed at the metacarpophalangeal joint, and a skin graft applied. He continued his work with the roentgen ray, and in 1911 there was a marked dermatitis and ulceration on the dorsum of the left middle finger (fig. 1) which was amputated. The following year a dermatitis developed on the little finger, and the involved area was excised and a skin graft applied. At that time the axillary glands were removed. When first seen by Dr. Kanavel (in 1914), amputation of the arm at the shoulder was advised; this the patient refused. Accordingly, the ring finger was amputated, the second, third and fourth metacarpals removed and the axilla again dissected. Metastases were found in the axillary glands. The process was not arrested, and the patient again consulted Dr. Kanavel who repeated his advice of the year previous, namely, amputation at the shoulder. This advice was again refused, and Dr. Kanavel amputated the forearm below the elbow and again dissected the axilla. The condition promptly recurred and now, fully realizing the gravity of the situation, the patient consented to amputation at the shoulder girdle which was performed elsewhere during the latter part of 1915. The patient died from carcinoma two years later, in 1917, at the age of 50, approximately fourteen years after he began to use the roentgen ray and thirteen years after the first appearance of the dermatitis.

CASE 2.—Dr. —, aged 54, Wesley Memorial Hospital, service of Dr. Kanavel, was first seen in January, 1925, because of an ulcerating area on the dorsum of the left middle finger, enlarged axillary glands and hyperkeratosis on the backs of all the fingers of the left hand. Fifteen years previously the patient had worked with the roentgen ray which led, he thought, to the development of a hyperkeratosis. This condition caused no disturbance until about a year previous to examination, when a small area on the dorsum of the middle finger became ulcerated. He was given radium treatment for this, but no improvement was noted. Two weeks before entrance he noted a "soreness" over the left forearm

and four days later a good sized swelling appeared in the left axilla. There had never been any real pain or other subjective symptoms. The patient's mother, aged 93, had two or three epitheliomas of the face treated and cured by irradiation, and his maternal grandmother had a carcinoma of the lip. The general physical condition was essentially normal for a man of his age. On the middle finger of the left hand there were two indurated ulcers with hard raised edges (fig. 2). Several areas of hyperkeratosis were noted, and the nail on the index finger of the right hand was hard, cracked and dry. There were enlarged glands in the left axilla; none in the right. Epitrochlear glands were not palpable on either side. Roentgen examination of the chest revealed no pathologic changes.

On Jan. 21, 1925, the left middle finger was amputated and the distal one third of the corresponding metacarpal bone removed. The enlarged gland in the axilla was removed for frozen section. It was returned with the diagnosis of squamous cell carcinomatous infiltration, and accordingly the axilla was carefully dissected and all lymphatic tissue removed.

Fig. 1 (case 1).—Roentgen dermatitis and carcinoma of the hand, recurrence on middle finger following amputation of index finger for same condition.

The postoperative course was smooth. A small nodule on the dorsum of the ring finger of the left hand was removed during convalescence, but there was no record of what this proved to be. Microscopic examination of the tissue from the finger revealed a moderately infiltrative and not highly malignant type of squamous cell carcinoma.

A communication from the patient, two and a half years after operation, was as follows: "The only evidences of trouble are the numerous keratoses on the first and third fingers and on the back of the hand for which you suggested skin grafting."

CASE 3.—There has been some discussion as to whether or not this case should be included in the series as carcinoma. In my opinion the condition is carcinoma, certainly precarcinomatous. The patient, Dr. —, Wesley Memorial Hospital, service of Dr. Kanavel, gave the history briefly as follows: "From 1914 to 1918 I occasionally used the fluoroscope in reducing fractures and

in search for foreign bodies. Early in 1918, there appeared on the back of my left index finger some roughness which I was told was bichloride or novocaine dermatitis, and little attention was given the condition until 1920, when after the removal of a needle in the foot, numbness and keratosis developed and it was quite evident that the x-ray was the source of the trouble. Consultation with various dermatologists and their routine treatment was carried out for five years. The last year diathermy and mild quartz light were a finale before the development of a very painful keratosis at the base of the middle phalanx of the index finger which was resected and direct grafts of the Ollier-Thiersch type were laid in. Examination revealed squamous pearls of low grade degeneration. Four months later, Dr. — excised and grafted over the middle phalanx of the middle and ring fingers and suggested watching a hard nodule which had developed in the graft of the index finger. It was the index finger that caused me the greatest worry and which you so kindly resected widely with perfect results so that at short distance it is hardly perceptible. No telangiectases have developed within the graft area."

An oval piece of skin (a previous Thiersch graft) was removed from the dorsum of the left index finger in June, 1927; the area after grafting is shown in figure 3. At the time of operation it was thought that the nodule, which was

Fig. 2 (case 2).—Roentgen dermatitis with carcinoma on the dorsum of the left middle finger of a physician.

palpable under the previous graft, might well be carcinomatous, and a frozen section was made through the skin removed, indeed through several areas of the graft, especially through the nodule, and no evidence of malignancy was seen. No epithelial cells were found in the deep tissue, and the diagnosis of chronic inflammation was made. Because of this it was thought that simple wide local removal of the previous graft with some of the healthy skin beyond it was ample. This was done and a free full thickness graft applied. The graft took well, there was no slough and ten days after operation the appearance was as shown in figure 3. The excised skin was saved; some of it was prepared in the laboratory as routine material and paraffin sections were made. Other pieces were saved and prepared later during the fall with the view of studying the changes in the transplanted skin from the earlier operation. In a few of the latter sections there appeared a picture which had not been seen in any of the numerous ones made at the time of operation, and which at once made the diagnosis of the process confusing. The histologic picture is shown in figure 4. There were epithelial cells which tended to form pearl-like structures; they were at an abnormal place for such cells and although they did not look very active and showed no mitosis, they had remained fairly viable for a long time, as the graft had been applied over a

year previously. The sections were shown to the members of the Department of Pathology of Northwestern University (Prof. F. R. Zeit, Prof. J. P. Simonds, Ass't. Prof. H. F. Fishback and Ass't. Prof. E. B. McGlumphy). The following is an epitome of the opinions given on the pathologic condition of the tissue: One of them was emphatic in his diagnosis of squamous cell carcinoma; another thought it was carcinoma; a third would not commit himself on the pathologic process but seemed inclined to think it might not be malignant, while the fourth was sure it was not malignant and that the epithelial cells found might well be epithelial cell inclusions (such as are found in implantation cysts).

As noted, I am inclined to look on the condition as carcinoma, and the patient has been advised of the disagreement as to the exact nature of the condition and told to return at the sign of any change.

CASE 4.—Dr. —, aged 61, Wesley Memorial Hospital, service of Dr. Kanavel, entered the hospital on Feb. 12, 1928. He had been exposed to the action of the roentgen rays during the fourteen years between 1910 and 1924, but experienced no disturbance until about 1920 (ten years after starting to use the roentgen ray), at which time a stubborn dermatitis developed on the dorsum of the left index and middle fingers and on the back of the right hand. About four years later, a rapidly

Fig. 3 (case 3).—Free full thickness graft applied over the middle and part of the distal phalanx after excision of the recurrent nodule in a previous graft. Roentgen dermatitis (with carcinoma?).

growing nodule appeared over the distal interphalangeal joint of the left middle finger about which he consulted a dermatologist, who advised amputation. Microscopic examination at that time was not definitely positive for carcinoma though many areas about the borders were suspected of being malignant. A year and a half later a warty growth (microscopic diagnosis not known) was removed from the dorsum of the right hand. Six months before the present admission a similar warty growth appeared on the dorsum of the middle phalanx of the left index finger. The nodule was fairly sensitive to pressure, easily irritated by soap and water, was about the size of a pea, rough and granular and presented numerous small black "coal spots." The skin on the backs of the hands was fairly rough, and numerous hyperkeratotic areas were present, especially on the right hand. The left index finger was amputated, and the most prominent areas of dermatitis on the back of the right hand were excised. Microscopic section of the nodule showed a squamous cell carcinoma; the small bits of skin from the opposite hand showed areas of hyperkeratosis but no malignancy.

CASE 5.—(Seen in consultation by Dr. Kanavel. History through the courtesy of Dr. O. L. Pelton, Jr., of the Pelton Clinic, Elgin, Ill.) In 1913, the patient, Dr. —, developed multiple abscesses on the backs of both hands following an

autopsy. Whether or not this had any etiologic relation is difficult to say, but shortly after the abscesses healed an eczema developed on both hands, especially severe between the fingers. This the patient treated and cured with the roentgen rays. The hands were normal and gave him no further trouble until 1920 or 1921, when the eczema recurred, and as it was not especially severe, it was treated with

Fig. 4 (case 3).—Photomicrographs of section of the skin graft removed from the dorsum of the index finger. The nest of questionably malignant epithelial cells is shown in the center of *A*; this is reproduced under higher magnification in *B*.

salves and ointments for several years. In August, 1927, the eczema became troublesome, and the physician again applied the roentgen rays, giving himself four treatments of five minutes' duration (75 inch [182.9 cm.] distance and 5 milliamperes) on four alternate days. As a result of these treatments the hands became considerably swollen, the nails came off and there was sloughing of the superficial layers of the skin. Despite the severe reaction, the hands healed in

about two months, leaving only a small ulcer on the back of each. In March, 1928, the physician used the quartz light, to which he knew himself to be hypersusceptible, in an effort to cure the ulcerations. Four quartz light treatments were given, and an almost immediate slough of the skin of the dorsum of both hands resulted. This reaction was more severe on the right side and was associated with intense pain, which required morphine at times. In May, 1928, the lesions were curetted, and on microscopic examination specimens of the material given to Dr. Kanavel were found to be carcinomatous. On May 16, the right hand was amputated through the lower third of the forearm. The left hand (fig. 5) was becoming progressively worse and will also probably require amputation.

In this case there was a combination of factors. There was first the initial postmortem infection which may or may not have had anything to do with the dermatitis. Then came exposure to the roentgen rays which apparently cured the "eczema" which remained absent for six years. On its recurrence, it was again exposed to the roentgen ray and after an extremely severe reaction finally cleared

Fig. 5 (case 5).—Carcinoma on the dorsum of the hand following eczema, with roentgen and ultraviolet treatment. Both hands were involved.

up with a resulting slight ulceration on both hands. This was again exposed to irradiation, this time ultraviolet, to which the patient knew himself to be susceptible because of experience following sunburn. This stimulation was followed by sloughing and ulceration of both hands which was shown to be carcinoma necessitating amputation of one hand and no doubt eventual amputation of the other.

CASE 6.—Dr. —, aged 46, consulted Dr. Kanavel because of an infected amputation stump on the middle phalanx of the right middle finger, an excised ulcer on the right index finger and keratoses over the backs of the fingers and dorsum of both hands. He gave the following history: Beginning from eighteen to twenty years before examination he had used the roentgen rays extensively in the reduction of fractures and in the search for foreign bodies. He noted no disturbance with the hands for a number of years and took no precaution to shield himself from the effects of the irradiation. About eight years before consultation his use of the roentgen rays was more restricted, owing to the advent of adequate laboratory facilities, and he exposed himself only occasionally. From five to six years before consultation, however, he noted numerous areas of keratosis appearing on the dorsum of both hands and fingers. These occasioned him little discomfort

and never broke down until two years before examination, at which time a patch of keratosis over the distal interphalangeal joints of the right middle finger broke open and bled slightly. Under ordinary care this crevice healed, though it reopened from time to time. Recently, he had noted burning of the hands following exposure to the roentgen rays. Three weeks before examination he consulted a dermatologist because the ulcer on the right third finger occasioned him a good deal of pain. Amputation of the finger, excision of a large area on the right index finger and excision of keratotic spots on the other fingers and dorsum of both hands were advised. The finger was amputated and the area on the index finger excised. Nothing, however, was done with the areas of keratosis.

Examination showed many areas of roughness over the backs of both hands, especially marked on the fingers where certain of the areas were fairly large, markedly scaly and with a tendency to the formation of fissures. The right middle finger was large and swollen, the terminal phalanx and half of the middle phalanx had been amputated, and the operative wound discharged a moderate amount of seropurulent secretion. A healing linear incision was present on the ulnar surface of the right index finger. An axillary gland was palpated on the right side, but this the patient said had been present for a number of years. No glands palpated in the left axilla or in the epitrochlear regions of either side. Microscopic section of the ulcer excised from the index finger and of the tissue from the amputated middle finger showed deeply infiltrating squamous cell carcinoma.

CASE 7.—Dr. —, about 50 years of age, overexposed the dorsum of the left hand to the roentgen ray approximately twenty-five years previous to the development of definite signs of malignancy. From eight to ten years after this overexposure, he noted a tingling or slight burning sensation on the dorsum of the hand following any exposure to roentgen radiation. During the fall and winter months fissures tended to develop on the backs of the fingers. On June 30, 1927 (approximately twenty-five years after the initial overexposure), the left ring finger was slightly injured in an automobile accident, the injury occurring over the dorsum of the terminal phalanx. This area refused to heal, became ulcerated and despite fulguration and curettage remained stubbornly indolent. After about six months the physician had the finger amputated through the first interphalangeal joint. A microscopic section made of the ulcer showed it to be an epithelioma. A severe infection followed this operation, and it became necessary to amputate the rest of the finger and its metacarpal bone. Sometime in March, 1928, the epitrochlear glands on this side became enlarged, and at the suggestion of Dr. Kanavel that this was a metastasis it was removed and found to contain carcinomatous cells. After a somewhat slow convalescence from these various operative procedures the patient went to the Mayo Clinic where the axillary and pectoral lymph glands were radically removed. One metastasis was found here.

To be noted in this case were the long period of latency from the initial irritation to the development of symptoms, the presence of lowered vitality, and low grade infection in the skin and subcutaneous tissues, which prevented healing of a minor injury and led to the development of a severe infection of the hand requiring amputation of the finger. Quite important was the development of an involvement of the epitrochlear gland which from the presence of the infection on the hand might well have been taken to have been inflammatory had not Dr. Kanavel suggested the possibility of malignant infiltration. Despite the frequent assertion that the glands are inflammatory it appears that thorough search of the enlarged axillary glands, as in this case, will often reveal some malignant cells. Glandular involvement, whether proved malignant or not, has too definite an effect on the prognosis to be disregarded or to warrant the assumption that it is purely inflammatory.

CASE 8.—Dr. —, aged 60, Wesley Memorial Hospital, service of Dr. Kanel, was admitted to the hospital on June 26, 1928, because of a roentgen dermatitis, on the dorsum of the left hand, of fourteen or fifteen years' duration. In 1905, the patient began to use the roentgen rays for fluoroscopic purposes and continued to do so until four or five years before examination. During the twenty years of exposure he had never taken precautions to protect the left hand in which he held the fluoroscopic box, from the action of the rays. He first noted a dermatitis in 1913 or 1914, or about eight or nine years after he began to use the roentgen rays. While he was in the army (1917-1919) and not so exposed to radiation, the condition improved; however, when he returned to civilian practice and the use of the fluoroscope, the dermatitis again appeared with its original vigor, and after a few years led him to discontinue the use of the fluoroscope. Various ointments were tried but without result, and the roughened areas had been shaved off at times but had promptly recurred. The condition first made itself apparent on the dorsum of the middle and index fingers of the left hand as smooth, shiny, reddish-pink areas in the skin with a white scaling spot in the center. After a time the redness

Fig. 6 (case 8).—Roentgen dermatitis and carcinoma on the dorsum of the index, middle and ring fingers; numerous keratoses on the dorsum of the hand.

disappeared and a brownish keratosis or wart remained. Some of these keratotic areas had broken down by cracking, acting, the physician said, like chilblains, leaving crevices which would not heal readily, though some had closed over and broken down repeatedly. During the past year, several crevices had appeared on the index finger in particular which had refused to heal.

Examination revealed the usual conditions of roentgen dermatitis, especially marked over the dorsum of the index and middle fingers, but also apparent on the ring finger and back of the hand. Many of these spots were scarcely raised above the surface, and were of such a slight difference in color from the rest of the skin that they could be detected only by palpation. Others of the keratoses were more marked, and over the index, middle and ring fingers there were several crevices which had refused to heal (fig. 6). The skin generally on the hand was somewhat rough and did not have the pinkish-white clearness of normal skin, but, as the physician remarked, looked dirty. General examination failed to show any evidence of involvement of the lymph glands in the axilla or epitrochlear region, and the lung fields were clear.

In view of the chronicity of the lesions and because several of them had broken down already and had failed to heal, Dr. Kanel felt that excision of the skin

over the backs of the index, middle and ring fingers was advisable. This was done and the hand was placed in the thigh with the fingers in the pockets (fig. 7). After three weeks the pedicles were cut loose and the hand freed, the graft having taken well.

Numerous sections taken from the skin removed showed the pathologic characteristics of roentgen dermatitis, thickening of the epidermis and hyperkeratosis, round cell infiltration of the corium and marked atypical epithelial downgrowth. Early squamous cell carcinoma was found in several places; fortunately no invasion was evident in the subcutaneous fat.

Fig. 7 (case 8).—Scheme of operation. The skin over the dorsum of the index, middle and ring fingers has been excised well back into healthy tissue, leaving three moderately sized defects. On the volar surfaces of these fingers Thiersch grafts are sutured, raw surface outward, and the fingers slipped into three pockets on the lateral surface of the thigh. The Thiersch grafts cover to some extent the raw surfaces of the thigh, thus facilitating repair of these areas after release of the fingers.

#### B. RADIUM AND ROENTGEN DERMATITIS WITHOUT MALIGNANCY

CASE 9.—Dr. —, a curietherapist, seen by Dr. Kanavel in 1922 or 1923 because of extensive necrosis of the thumb, had subjected the hand to numerous though brief exposures to radium. A warty growth had occurred on the thumb, and because of the attendant pain the nerves at the base had been injected elsewhere with alcohol. Presumably due to vascular injury from this injection the

thumb became necrotic and amputation was necessary. Microscopic sections of the warty growth (not available) failed to reveal any criteria for malignancy. No further complications developed.

CASE 10.—Dr. —, aged 47, Wesley Memorial Hospital, service of Dr. Kanavel, twenty-five years previous to examination incurred a roentgen burn on the dorsum of the left hand. This condition improved greatly, however, under palliative treatment and caused little disturbance until during the war (1918), at which time he used the fluoroscope considerably in extracting foreign bodies. At that time the accompanying infection led to an osteomyelitis of the left middle finger for which the distal phalanx was amputated. The acute process cleared up following this operation, but the patient suffered from keratosis and cracking of the skin of the left hand ever since. The keratosis became progressively worse and following a slight injury received during an operation a large area on the left index finger became fissured and then ulcerated. It was because of this ulcer that the patient consulted Dr. Kanavel, who advised amputation of the finger at the metacarpophalangeal joint. The wound resulting from this amputation healed slowly; a slough of the flap developed, and healing took place only after considerable time. The wound had not broken down since its closure. The microscopic sections of the finger, examined by Dr. J. P. Simonds, gave no definite criteria for malignancy; however, they did present definite changes which have been looked on by many investigators as the forerunners of carcinoma (fig. 8). Most marked perhaps was an obliteration of many of the blood vessels of the corium, a process which has been considered characteristic of roentgen dermatitis and carcinoma. Ulceration, hyperkeratosis and hyalinization of the connective tissue in the corium were noted.

The point of special interest in this case was susceptibility to infection shown by the keratotic skin. At the time of the first ulcer there was an osteomyelitis; at the time of the second ulcer the whole finger was so involved as to necessitate amputation. The tissues well back of the ulcer were infected and poorly resistant.

CASE 11.—Dr. —, Wesley Memorial Hospital, service of Dr. Kanavel, consulted Dr. Kanavel because of a dermatitis following a roentgen burn sustained from fifteen to sixteen years previously, and because of a chronic ulcer on the index finger of the left hand. He had been accustomed to using the roentgen rays considerably for therapeutic purposes and had experienced no discomfort until after a series of rather severe exposures to the index finger and thumb of each hand. He had been obliged to hold a patient's mouth open for irradiation of a carcinoma of the lip. After four exposures during a course of three weeks a severe dermatitis developed on the fingers exposed and could be controlled only with difficulty. He eventually discontinued the use of the roentgen ray for therapeutic purposes but did use it for fluoroscopy, despite the presence of stubborn hyperkeratotic spots on the thumb, index and middle fingers of both hands. About six years before examination, ulcers developed on the backs of the index and middle fingers of the left hand, one on the medial surface of the index finger near the nail bed and one over the distal interphalangeal joint of the middle finger. Mild antiseptic dressings were applied, but despite this, healing was not permanent; the areas closed over and broke down intermittently. Three years previously the physician had excised the ulcer on the index finger, and this area remained healed. The ulcer on the dorsum of the middle finger, however, was extremely painful and considerably larger than that on the index finger. Several days previous to admission the ulcer on the middle finger was excised elsewhere with view to covering the area later with a skin graft. Due to an infection the graft was not applied. On examination, an ulcerating area, 2.5 by 2 cm., was found over the distal interphalangeal joint of the left middle finger. The floor was red,

granular and discharged a seropurulent secretion. The ulcer did not have the appearance of malignancy, but the fact that this had resulted from an excision vitiated the diagnostic value of its gross appearance. Numerous areas of hyperkeratosis were seen over the backs of the thumb, index and middle fingers and to some extent over the dorsum of both the right and the left hand. The scar resulting from the excision of the ulcer from the index finger was fairly rough and the skin about it was hyperkeratotic. No axillary or epitrochlear glands were present. A diagnosis of roentgen dermatitis and possible carcinomatous degeneration was made. Dr. Kanavel amputated the middle finger at the metacarpophalangeal joint, and excised numerous areas of hyperkeratosis from the hands on Jan. 18, 1928. Microscopic sections of the tissues removed showed no evidences of malignancy. The ulcer was a chronic inflammatory process and sections including the bone failed to reveal any epithelial infiltration.

Fig. 8 (case 10).—Roentgen dermatitis, no carcinoma. Photomicrographs of excised skin. In *A* is noted the necrosis of the floor of the ulcer, and the marked round cell infiltration of the thickened corium. In *B* the corium is seen to be fairly dense and the epidermis irregularly proliferated below and hyperkeratotic on the surface. In *C* is seen the frequently present vacuolization of the prickle cell layer.

#### PATHOLOGY AND PATHOGENESIS OF ROENTGEN AND RADIUM DERMATITIS AND CARCINOMA

The interesting pathologic characteristics of roentgen dermatitis and their bearing on the development of carcinoma which have been described in the work of Porter and Wolbach<sup>21</sup> deserve summarizing at this point. Reasoning from experiments conducted on guinea-pigs

21. Porter, C. A., and Wolbach, S. B.: X-Ray Lesions and Their Surgical Treatment, *Tr. Am. Surg. A.* **41**:444, 1923; discussion, p. 467.

and from observations made on pathologic conditions of man, Wollbach<sup>22</sup> was able to construct a logical course of events in the production of the roentgen carcinoma in man. Presumably, the cuticle is transparent and unaffected by the roentgen rays, the full effects of which are felt on the corium and subcutaneous tissues. It would appear that collagen is particularly susceptible to the action of the rays and that this tissue, regardless of its location—corium, subcutaneous tissues and blood vessels—becomes swollen and later is replaced by dense tissue rich in elastic fibers and poor in cells. This process is particularly noted in the corium and blood vessels. The corium becomes thick and dense and the blood vessels obstructed and often obliterated. Hair follicles, sweat and sebaceous glands disappear. Small foci of necrosis occur in the corium, due probably to circulatory disturbances in which numerous areas of telangiectatic vessels develop. Occasionally, thrombosed telangiectases have been found in these necrotic spots which frequently become infected. With the presence of infection there is a round cell (perivascular) infiltration of the corium. The areas of necrosis are not repaired from below as one would expect, but a proliferation of the epidermis is found in and about them. Wollbach assumed that the epidermal proliferation which is invariably present is caused by the fact that over these areas of necrosis and dense corium the nutrition of the skin is seriously impaired. The cells are separated from the normal sources of food supply, and in seeking a blood supply push further and further into the corium. The epidermis is imperfect, the long retal pegs and the imperfect keratinization are typical. Over a period of years the epidermis is constantly called on to repair defects much in excess of the normal, and it is not surprising, therefore, that sooner or later, malignant changes would take place, not as a sudden acquisition of abnormal proliferation but as the result of the requirements put on it by the pathologic condition of the supporting structures. Whether this view, sponsored particularly by Wollbach, is the correct one is a difficult matter to settle. Certainly the known facts can be explained on this basis. The multiple occurrence, the long delay before malignant changes and the recurring appearance of numerous carcinomas in different places would all fit in perfectly with the explanation of the pathogenesis as previously outlined (figs. 8 and 9).

My experience rather coincides with that of Cole,<sup>20</sup> and I am inclined to agree with him "that if the total figures of chronic roentgen-ray and radium dermatitis in medical men and technicians could be ascertained, it would far exceed any figures ever reported." There are probably two causes for this. In the first place none of the recent patients has been a professional roentgenologist, but they have all used the roentgen

---

22. Wollbach, S. B.: A Summary of the Effects of Repeated Roentgen-Ray Exposures upon the Human Skin, Antecedent to the Formation of Carcinoma, *Am. J. Roent'genol.* **13**:139, 1925.

Fig. 9.—Roentgen carcinoma; *A* (case 8), shows the necrosis with subsequent round cell infiltration just beneath the epidermis, and the abnormal epithelial pegs growing down into the area. *B* (case 11), roentgen dermatitis with more marked epithelial proliferation into the corium at the edge of the ulcer; no definite criteria for malignancy. *C* (case 7), roentgen carcinoma.

rays in conjunction with their regular practice. It is hardly to be expected that one who is not devoting his entire time to this work would take the precautions that the professional roentgenologist would take. Even with the best intentions it is a great temptation to omit the use of gloves and other precautionary measures, particularly when pressed for time. There is also the factor of latency, which has been emphasized by all who have written on roentgen carcinoma (Matas<sup>23</sup>). By this is meant that between the period of exposure to the roentgen rays and the development of a dermatitis there is a certain interval which elapses before the dermatitis develops. In the case of severe burns this interval is short; in the case of a chronic dermatitis the interval is longer. Several months or even years may intervene before the lesions become apparent.

It is scarcely necessary to go into detail regarding the history of a case of roentgen dermatitis and the carcinoma developing from it. The several case records here included are sufficiently typical. The lesions occur first as keratosis and telangiectasis on the dorsum of the fingers and hand, rarely extending above the level of the cuff which appears to afford protection against the rays. Between the onset of exposure and the development of the dermatitis a considerable period may elapse—usually several months or even years. It appears that once the dermatitis has developed it is nearly self-sustaining in that a permanent injury to the corium has been incurred which calls forth continuous reparative changes on the part of the epidermis. Usually, the warning dermatitis is treated with salves, or worse, by means of ultraviolet irradiation or even the x-rays. Most frequently the patient does not discontinue his use of the roentgen rays, probably because the true nature of the lesion is not recognized. The process may remain fairly stationary for years even with constant exposure, but sooner or later, in a large percentage of cases, certain changes take place which presage malignancy. These changes usually take the form of cracking of one or several areas of keratosis. Rarely, a definite small ulcer is formed. Even here spontaneous healing may occur, and some lesions after healing may never break down. Others may break down and heal repeatedly; still others may never heal entirely and, though not rapidly progressive, may slowly enlarge. This persistency of ulceration may be assumed to be the indication of beginning malignant changes and may not occur for five or ten years (rarely ever longer) after the appearance of the dermatitis.

After the appearance of malignancy in one area other carcinomas develop, and here, in the multiplicity of the carcinomas, lies the treacherousness of the condition. Here also lies the secret of the treatment and the explanation of the numerous operations usually necessary. It is not the recurrence of the carcinoma at the original site but the develop-

---

23. Matas, Rudolph: Remarks on the Delayed or Remote Appearance of X-Ray Burns After Long Periods of Latency, *Am. J. Roentgenol.* 13:37, 1925.

ment of new cancers at other sites that calls for further operation and should point to the proper procedure in treatment.

Radium may lead to changes similar to those caused by the roentgen rays, but such case reports are few (Wakeley<sup>24</sup>). The possibility of this occurrence, however, should be kept in mind.

#### PROGNOSIS OF ROENTGEN CARCINOMA

As Porter<sup>19</sup> pointed out long ago roentgen carcinoma is characterized by the multiplicity of lesions, and it appears that it is this factor which determines the prognosis. That the condition is serious is emphasized by the statistics of Porter. In fifty-one instances of roentgen dermatitis, five were not malignant, while forty-six were malignant. Twenty-four, or 52 per cent, of the forty-six malignant cases presented extensive recurrence or metastases and ended fatally; twenty, or 43.5 per cent, of the patients were cured. Again the fact that all such neoplasms are squamous cell in type is another factor which adds to the gravity of the condition. The underlying pathologic process of the dermatitis, not in itself malignant but which leads to malignant changes in the epidermis, is present in multiple areas over the backs of the hands and fingers, and areas not visible at the time of operation may develop in a few weeks into keratoses and carcinoma. Unless the hand is carefully watched and every spot of keratosis and roughening removed as it develops, there is always the danger of the recurrence of carcinoma. The original areas operated on do not recur as a rule, providing the operation has been thorough and frozen section checks made of the excised tissue. One can feel practically certain that recurrence at these places will not occur. From clinical experience glandular enlargement appears frequently to be due to carcinoma. In four cases in which the glands were enlarged, operation was performed on three patients (one was seen only in consultation), and in each malignant infiltration was found. In the fourth case the patient thought the gland had been present for many years and had followed an infection. The presence of this complication, however, must make the prognosis much more serious (a fact which will be brought out later in the discussion of glandular enlargement).

#### GROUP A II: CARCINOMAS OF THE HAND FOLLOWING IRRITATION, EXCLUSIVE OF ROENTGEN RAY AND RADIUM

Carcinomas developing on the basis of some trauma, acute or chronic irritation, scars, or other condition, form a fairly large group of cases, containing 98 (38 per cent) of the 255 reported instances of carcinoma of the hand. In my series there were 7 such carcinomas. Particular attention is called in the following case reports to 5 cases, 2 carcinomas of the palm and 3 carcinomas of the nail-bed.

24. Wakeley, Cecil P. G.: Radium Carcinoma of the Thumb, *Brit. J. Surg* 14:677, 1927.

Curiously, none of the three lesions of the nail-bed was a melanoma, although one had the appearance (clinical) of a melanocarcinoma.

CASE 12.—Mr. W. L. H., a pedler, Wesley Memorial Hospital, service of Dr. William Schroeder, was seen on April 17, 1912, because of a fungus-like growth on the left forearm and axilla. At the age of 3 he had fallen into a kettle of maple syrup, burning his hands and forearms. The right hand and forearm healed up very well, but the left had given him trouble ever since the accident. The skin over the wrist hardened and peeled off leaving a pinkish irritated area which later covered over again. Two years before examination the area enlarged, became purulent and ulcerated. A physician was consulted, who excised the ulcer and removed the glands from the axilla. Eighteen months later the scar broke down and the axilla began to discharge pus. Unfortunately, the record stops here.

CASE 13.—Mr. K., aged 76, Wesley Memorial Hospital, service of Dr. William Schroeder, entered the hospital on July 3, 1925, complaining of a large swelling on the dorsum of the right hand. Three years previously, while working with lumber, he ran some fine pine slivers into the back of the right hand. The pieces of wood did not go in very deep—"just under the skin"—and the patient removed them himself and went on about his work. The injury seemed to heal up well, leaving fine white streaks of scars. One year later (two years previous to admission) a small papule about the size of a split pea appeared in one of these scars. This papule was subjected to frequent injuries during work, the top being torn off, leaving a whitish-pink area which did not bleed profusely. Various salves were applied but had no effect on the lesion. In September, 1924, about ten months before admission to the hospital, the area was about the size of a quarter and was not elevated above the level of the skin. About this time, however, it started to grow rapidly. There had been no loss in weight. There were no other complaints, and the past and family histories were essentially negative.

Examination revealed an irregular, raw, bleeding mass, about the size of a small lemon, on the dorsum of the right hand. The area was hard and sharply defined from the surrounding tissues. The axillary glands on the right side were palpable, but the epitrochlears could not be felt.

Dr. A. J. Larkin applied 110 mg. of radium for twenty-four hours, following which the growth gradually sloughed out; one month after the application the patient was discharged. The wound at this time seemed to be covering over with granulation tissues. The patient was instructed as to the care of the wound and told to return in one month if healing had not taken place or if there were any evidences of growth. The patient died during the winter of 1926 and 1927 from cerebral hemorrhage. His family physician reported that there had been no return of the epithelioma.

CASE 14.—(Mrs. Emma B., from Northwestern University Medical School, Surgical Dispensary). A colored housewife, aged 49, entered the dispensary on Sept. 12, 1927, complaining of a swelling of the terminal phalanx of the left fifth finger of about nine months' duration. Nine months previously she had caught the finger between a table and chair, mashing it so severely that the nail was broken in half longitudinally. The nail came off four weeks after the accident, and the finger started to drain pus, ached, throbbed and was evidently badly infected. It was treated with salves and ointments by a physician, but the condition did not improve. Because of the severe pain which had been present almost continuously she came to the dispensary for advice and treatment, where she was seen by Dr. Hart. The terminal phalanx was swollen, red and inflamed, and a small granulating mass was seen in the area which had once been the nail-bed. A small piece removed for biopsy proved to be squamous cell carcinoma. No axillary or epitrochlear glands could be palpated. The finger was amputated at the metacarpo-

phalangeal joint under local anesthesia. There has been, to date (November, 1928) no evidence of recurrence.

CASE 15.—Mr. E. S. V., Mercy Hospital, service of Dr. F. A. Besley, seen in consultation by Dr. Kanavel, entered the hospital on Nov. 11, 1920, because of an ulcer on the palm of the left hand associated with a good deal of pain, a foul odor and bleeding. Four years previously the ulcer started as a small papule in a scar of many years' duration. The lesion gradually increased in size and eventually ulcerated with the production of considerable pus. There had been no loss in weight. The previous history was without notable events, and the general physical examination was essentially negative. On the palm of the left hand (fig. 10) was a large, deep, almost circular ulcer, with hyperemic borders, which discharged considerable amounts of foul smelling, yellow pus. The area was fairly tender to pressure, and the axillary and epitrochlear glands were palpable. The left arm was amputated at the junction of the middle and upper thirds and the axillary glands were removed. Healing occurred per primum. The pathologic condition was squamous cell carcinoma. Unfortunately, I have not been able to get in touch with this man since his discharge from the hospital.

CASE 16.—(Personal communication from Dr. J. S. Mason, of Urbana, Ill.) Mrs. C. K., aged 56, a milliner, had noted a thickened area on the side of the nail-

Fig. 10 (case 15).—Carcinoma of the palm developing on an old scar.

bed of the left index finger for some ten years, a spot constantly irritated by her needle while sewing. Several months before being seen by Dr. Mason, the area had become hard and thickened and a crust developed on it. When seen for the first time the lesion was red and swollen and looked a good deal like a chronic paronychia. There were no palpable lymph glands in the axillary or in the epitrochlear region and no processes in the chest. She was told that it was not a simple infection and was advised to have the finger amputated which she refused to allow and went to some other physician who gave her violet ray treatments, which only aggravated the condition. She finally returned to Dr. Mason who amputated the finger along with the distal third of the metacarpal bone. Microscopic study of the tissue showed it to be a squamous cell carcinoma. The wound was slow in healing, though eleven months later it had healed well and there was no evidence of return.

CASE 17.—(Courtesy of Dr. Frank M. Mason, Danville, Ill.) Mr. F. DeM. was examined in February, 1928, because of a chronic granulating tumor of the nail-bed of the right thumb, which had been present for six years following a severe mashing injury. Twice during the previous six years the thumb had been treated elsewhere, and small bits of the nail removed in the hope of clearing up what was thought to be a chronic paronychia. On examination a cauliflower-like mass, the

size of a walnut, was seen occupying the area of the nail-bed (fig. 11); no nail could be seen. In parts the tumor was reddish and granular; in other parts it was dark and black and suggestive of a melanoma of the nail-bed, which was the pre-operative diagnosis. There were no palpable epitrochlear or axillary lymph glands, and the chest was clear. The thumb was amputated at the metacarpophalangeal joint and although healing was slow, probably because of coincidental infection in the tumor, the wound finally closed. The microscopic section examined by Dr. E. A. Kraft of Danville, and by the members of the Pathology Department of Northwestern University, was diagnosed as squamous cell carcinoma.

CASE 18.—(Courtesy of Dr. J. J. Lebowitz, Chicago.) Mr. A. M., aged 64, was first examined by Dr. Lebowitz in August, 1928, because of a large bleeding tumor of the right hand, a loss of weight, strength and appetite and a troublesome diarrhea. About twelve years previously, the patient ran a nail into the right palm between the fourth and fifth metacarpal bones. The resulting wound healed in a few days and gave him no further trouble until four years later when he noted that a callus had developed on the site of the injury. No change occurred in the callus for three years, at which time (seven years after the initial trauma) the area broke down and produced an ulcer, the size of a finger-nail, which was

Fig. 11 (case 17).—Carcinoma of the nail-bed of the right thumb following a mashing injury.

treated with radium. Healing was fairly prompt, though some pain and tenderness persisted. The ulcer recurred, however, and was again treated with radium; although the response was prompt the area repeatedly broke down and during the five years since its appearance had been subjected to radium therapy about fifteen times, the last time during the early part of 1927. In September, 1927, after a year's complaint, the patient was operated on by a competent urologist for an enlarged prostate which was shown to be malignant. During the period of hospitalization, the ulcer on the palm attained the size of a quarter, was stubbornly resistant to treatment and eventually became cauliflower-like and attained enormous dimensions, entirely filling the palm. Recently, the mass on the palm has been bleeding profusely, at times actually spurting, and hemostasis has been difficult. About two months previous to examination the patient suffered a sudden attack of severe diarrhea, which lasted for about twenty-four hours. For five weeks after this attack the patient said that he had no bowel movements, though he soiled his linen in passing flatus. Another severe attack of abdominal pain was followed by several copious movements after which he had daily movements, at times without control. Blood had been noted in the stool lately. Besides the complaint mentioned, the patient had a "sore" on the nose for five years, a "sore" on the small of the back for five years and an ulcer on the left buttocks for twelve years. The patient was markedly emaciated and pale, with a lemon tinge. There was a flat ulcer on the

left side of the nose near the inner canthus of the left eye, an ulcerating area on the left buttock and a raised dull red lesion not ulcerated on the small of the back. The entire right palm was filled by a large, freely bleeding, cauliflower-like mass, which emitted a foul odor. A rectal examination was not made. The diagnosis made by Dr. Lebowitz was: Carcinoma of the right hand, epithelioma of the nose, buttocks and back, and recurrent carcinoma of the prostate. The hand was amputated through the middle third of the forearm.

Because of the great rarity of palmar carcinoma, a rather full description of the gross pathologic condition is given. The palm was almost completely covered by a massive cauliflower growth, 9 by 9.5 cm. in lateral extent, and projecting from 2.5 to 3 cm. above the palmar level of the hand (fig. 12). The mass was somewhat rounded and lay on the radial side of the palm; distally the tumor reached the proximal creases on the ring and index fingers, projected as an exuberant nodule between the index and middle fingers and extended over the proximal half of the proximal phalanx of the index finger. Proximally, the mass covered the thenar eminence and extended to the level of the carpometacarpal joints. On the ulnar side the tumor reached the radial border of the hypothenar

Fig. 12 (case 18) —Carcinoma of the palm developing in the scar of an injury from a puncture wound.

eminence. On the radial side, however, in the first interosseous space the mass rolled over the border of the hand onto the dorsum and projected here as a tumefaction, the size of an egg, over the dorsal surface of the second metacarpal bone. Over the surface and in the crevices of the tumor was a quantity of dark mucoïd material, probably pus hardened by the formaldehyde.

To ascertain the extent to which the tumor had invaded the tissue three transverse incisions and one longitudinal one were made through the hand (fig. 13). The first section made through line *a*, passed just proximal to the metacarpophalangeal articulations and was easily made with the knife through bones and all. Cuts *b* and *c* required the saw for all the metacarpals except the second which was soft enough to be cut by the knife.

Figure 14 shows the appearance of the section through plane *a*. This section was dominated by the grossly evident carcinomatous infiltration which stood in contrast by its grayish white color to the more yellow appearance of the little remaining normal tissue of the hand. From the radial border of the hand to the radial border of the third metacarpal no normal tissue was recognized, with the exception of a small spicule of the second metacarpal bone, the infiltrated index flexor tendons and a short stretch of skin on the dorsum. The evidently cellular

carcinoma was fairly friable and presented a large area of necrosis in the depths. No nerves or blood vessels were seen in the tumor; there was no visible blood supply, and the normal vessels had been invaded and replaced by the tumor. At the border of the hypothenar eminence the tumor appeared to have been abruptly halted by the deep vertical sheet of the palmar fascia; the fat over the eminence, however, was not normal in appearance and was undoubtedly infiltrated with carcinoma. All of the tissue volar to the third and fourth metacarpals was densely infiltrated with carcinoma which had also extended into the space between the third and fourth metacarpal bones. The flexor tendons of the middle and ring fingers had no sheath left and were displaced and invaded by the neoplasm.

Section *b* (fig. 15) was particularly interesting in that it showed the resistance which the fascial sheets of the hand have to carcinoma invasion. Thus, the vertical sheet of palmar fascia which helped to separate the thenar from the midpalmar

Fig. 13 (case 18).—Planes *a*, *b* and *c*, of section illustrated in figures 14, 15 and 16.

space stood out clearly between the carcinoma on the radial side and the uninvaded interosseus muscles on its ulnar side. More superficially, however, the palmar aponeurosis over the radial side of the hand had been entirely replaced by carcinoma, and the midpalmar space was on the way to being invaded from above. At the borders of the tumor mass, where it overhung the surface of the hand, it was possible to trace the skin as a grayish white streak for a short distance into the tumor.

Section *c* (fig. 16) shows the carcinoma coming up to the fascia over the thenar muscles at which point it stopped. The carpometacarpal joint of the thumb was not invaded nor was the tissue dorsal to it. The radial artery appeared intact, but the index flexor tendons were firmly encased in the neoplasm.

The roentgenogram (fig. 17) reveals very well the extent of the carcinoma which stood out darkly against the normal soft tissues. The proximal phalanges of the index and middle fingers were infiltrated by carcinoma and the third metacarpophalangeal joint was dislocated toward the ulnar side; practically the

whole second metacarpal bone was infiltrated with carcinoma, which in the region of the head of the bone had almost entirely replaced all normal bone tissue.

Besides these seven carcinomas there was an alkali ulcer of the hand, which, because of its stubborn persistence and refusal to heal even with fairly wide excisions, has been listed as a precarcinomatous ulcer.

CASE 19.—George F., aged 18, Wesley Memorial Hospital, service of Dr. Kanavel, first consulted Dr. Kanavel in January, 1928, because of a persistent ulcer on the dorsum of the left hand resulting from a caustic burn (presumably from potassium hydroxide or sodium hydroxide) sustained twelve months previously. The solution was immediately washed off but a gangrenous area the size of a silver dollar became quickly demarcated and gave him a great deal of pain. Alcohol dressings were applied by a physician, and it was thought that the lesion would soon heal. Instead, an ulcer developed which resisted all ordinary measures and after about nine months of conservative treatment was excised and the edges

Fig. 14 (case 18).—Section through plane *a* looking distally. The Roman numerals refer to metacarpals, of which the second is practically entirely replaced by carcinoma. The carcinoma (white area) is seen to have infiltrated two thirds of the hand at this area.

sutured together. The stitches soon pulled out, and an ulcer the same size as the previous one developed. The boy was accused of malingering, and in this connection was sent to Dr. Kanavel for consultation. When first seen there was an oval-shaped ulcer on the dorsum of the left hand, about the size of a large pumpkin seed, just between the metacarpophalangeal joints of the ring and index fingers and extending slightly distalward down into the web (fig. 18). The floor of the ulcer was red, granular and somewhat protrusive and secreted a thin seropurulent discharge. The edges were slightly elevated and rolled; the surrounding skin was reddened but not indurated. The ulcer was not adherent to the extensor tendons. The patient complained of occasional pain in the region of the ulcer and over the dorsum of the hand. The Wassermann reaction was persistently negative.

It was felt at first that excision of the ulcer and approximation of the edges of the skin with immobilization of the fingers would lead to healing; accordingly, the ulcer was excised along with its hardened base, and the fingers splinted in

Fig. 15 (case 18) —Section, *b*, about 15 cm more proximal. The apparent resistance which the deep sheet of palmar fascia, running volarward from the third metacarpal, offers to the infiltration of the carcinoma is interesting. Through the carcinoma proper, little normal tissue is recognizable.

Fig. 16 (case 18) —Section, *c*, passing parallel to long axis of palm through the base of the thenar eminences and central portion of the palm. The thenar muscles and the fascia covering them have resisted the growth which has completely surrounded the flexor tendons of the index finger.

extension. The area remained closed for several days and then opened up again. Mild antiseptic treatments were applied and the wound examined daily for evidences that the patient tampered with it, but there was never at any time any suggestion of this. Several months later the area was again excised, this time more widely, with the same results. It appeared evident that there was no element of malingering, and after a few weeks of ultraviolet therapy a pedunculated graft was applied to the area after wide excision. Although performed in one stage, the graft healed nicely and there is to date (seven months) no evidence of recurrence (fig. 18).

The pathologic changes of the ulcer, except for the flatness, resembled those of the telangiectatic granuloma a great deal; i. e., the skin on approaching the area

Fig. 17 (case 18).—Roentgenogram of massively infiltrative carcinoma of the palm. The carcinomatous tissue stands out darkly in contrast to the other tissues of the hand. The involvement of the second metacarpal, proximal phalanx of the index finger and base of the proximal phalanx of the middle finger with lateral dislocation of the metacarpophalangeal joint of the middle finger are well shown.

of the ulcer showed considerable irregularity, and the interpapillary portions of the malpighian layer dipped deeply into the corium in which a few isolated clumps of cells cut off by the section were occasionally seen. At the border of the ulcer the edges rolled under and turned downward or even backward on themselves and ended. No mitoses or suspicious irregularities of the epithelial cells were seen. The base of the ulcer was chronic inflammatory tissue, necrotic on the surface. There were numerous areas of round cell infiltration and some polymorphonuclear leukocytes. A few of the numerous vessels were thrombosed, and some had fairly thick walls (fig. 19).

Fig. 18 (case 19).—Alkali ulcer of the dorsum of the left hand; *A*, recurrence of the ulcer following three excisions during eleven months; *B*, six weeks after wide excision and application of the pedunculated flap. (No recurrence in seven months.)

Fig. 19 (case 19).—Photomicrograph of tissue from the edge of the ulcer shown in figure 18. Proliferation of the epithelial pegs into the fibrous and round cell infiltrated corium. There was no malignancy present microscopically.

## COMMENT

The group to which the preceding seven cases belong is made up of carcinomas developing on the basis of some previous irritation, trauma, acute and chronic inflammation, scars of various sorts, burns and dermatitis from medication. Ninety-eight, or 38 per cent, of 255 cases (roentgen ray excluded) are included in this group. In table 2, I have listed the ninety-eight cases reported in the literature (including my own) according to causative factor and sex.

Scars from burns are the most frequent single definite factor—nineteen of the cases. A striking characteristic is the great age of the scars in which carcinoma develops; the average duration for these scars is forty-two and three-tenths years, the longest being sixty-six and a half years and the shortest one-fourth year. In age the patients average

TABLE 2—*Group A: Types of Irritation and Trauma (Exclusive of Roentgen Ray and Radium) Given as Etiologic Agents Leading to the Development of Carcinoma of the Hand*

52.8 years for the males and 50.5 years for the females, from which it is seen that most of the burns were contracted during childhood. Industrial burns, such as are so frequently seen at present, may be confidently expected to lead to the development of a considerable number of carcinomas of the skin during the next twenty to thirty years. The factors present in scars from burn which predispose to the development of carcinoma are probably several. Whoever has dissected a burn scar from a hand, preparatory to replacing the area with a graft, is impressed by the extreme density of the scar tissue which has filled the area and which is constantly under considerable tension due to its compromising action on the movements of the structure involved. This factor must be an irritant to the thin, irregular epithelial covering. The scar tissue is poorly vascularized, and the skin which develops over it is thin and poorly nourished, easily traumatized and frequently subjected to trauma because of the elevation of the scar. The skin cannot glide over the hard adherent scar of which it forms a part and receives the full brunt of any trauma.

Lupus is also a not infrequent factor, ten of the ninety-eight patients having lupus on the hand with consequent carcinoma. Although in certain instances, as Coenen<sup>25</sup> suggested, the use of the roentgen ray in treating lupus has been a factor in determining carcinomatous changes, the development of carcinoma in patients not treated by irradiation shows that the lupus scar in itself is a potential danger. Chronic inflammation from the long presence of tuberculosis is one possible factor and an atrophic scar another. Whether tuberculosis of the skin in itself is a predisposing factor analogous to the influence syphilis bears to cancer of the mouth I cannot say.

Chronic inflammation other than tuberculosis accounts for twelve instances, eleven in males and one in a female. The most interesting and one of the most instructive of this type is the carcinoma developing on the basis of an "issue." It has in it the elements of a laboratory experiment. These ulcers, which were kept open, often from twenty to thirty years, by means of various irritants combined with the usual septic dressings of the day when such therapeutics were practiced, account for three of the twelve cases under this heading. Draining sinuses from osteomyelitic foci form a particularly treacherous source of carcinomas. The epithelial lining of the tract, often deep in the tissues, even close to or at the bone, may undergo malignant changes which develop unsuspected until a granulation-like plug at the orifice of the sinus or even a large cauliflower mass appears.

The history of a single trauma followed more or less closely by development of a carcinoma was found in eighteen cases; twelve of the patients were males and six were females. In looking over this series it would appear that infection must enter into it somewhere for in the ones so listed some chronic and apparently infectious process was produced, which stubbornly refused to heal. Carnett's<sup>26</sup> case directly followed an injury from a spiking from a baseball shoe. To this class of puncture wounds could be added the cases of Bunch<sup>27</sup> following a splinter wound, that of Adler<sup>28</sup> following pricking with a blackberry spine, those of Alquier and Halbroun<sup>29</sup> from a nail wound, and those of Verneuil and Doyen; case 18 is of interest in this respect. Bites from animals are frequently reported in the literature as the

starting points for a carcinoma of the hand; thus von Winiwarter<sup>1</sup> reported a carcinoma following a horse bite; Chassaignac a carcinoma of the thumb from a dog bite and Würz<sup>4</sup> a carcinoma of the forearm following a dog bite. Von Brunn's<sup>15</sup> case followed a pig bite and Fox's<sup>17</sup> a horse bite. Injuries to the nail-bed, either crushing in nature or pulling off of the nail, are given as the inciting cause in a case reported by Weiss, in that by Blakeway,<sup>30</sup> and in several cases in the series reported. (So far as I know case 14 is the first case reported of carcinoma of the hand in a negro.) The manner in which trauma may set up carcinomatous changes in the skin remains a mystery; the fact that so few carcinomas do develop from injuries makes one look toward the special predisposition on the part of the patient.

Scars of various sorts (not including scars from burns) are listed twenty-one times in the tables. Like the scars from burns, they may be many years old before carcinoma develops in them. Melchior<sup>31</sup> reported one which developed sixty-seven years after a pistol wound of the hand. Several such cases following gunshot injuries are on record to teach one the remote possibilities of such wounds. The age of these scars equals that from burns.

Chronic irritations, such as from an ingrown nail (Volkman<sup>9</sup>), pressure from scissors, from shoemaker's tools (Stahr<sup>32</sup>), from a needle or from a saw, have all been given as etiologic factors.

One case of carcinoma following a furuncle on the dorsum has been reported (Schneider in von Brunn<sup>15</sup>). Hartzell, in discussing the paper by Fox,<sup>17</sup> remarked that he had seen several following the appearance of carbuncles on the dorsum.

Occupational carcinomas of the hand are rare. Volkmann<sup>9</sup> reported two and Parker<sup>33</sup> reported one in a coal gas worker. Arsenical dermatitis, as is well known, may end up as cancer. The case reported by Nicholas, Gate and Lebeuf<sup>34</sup> occurred in a man, aged 53, who had taken large doses of solution of potassium arsenite (from 30 to 40 drops daily) for a period of five years. An arsenical dermatitis

developed, and on this basis a squamous cell carcinoma obtained. A case is illustrated by Pusey<sup>35</sup> in his textbook. Freezing was given by Franze<sup>13</sup> as cause for an ulcer which became carcinomatous. Hazen and Whitmore<sup>36</sup> reported a case of carcinoma of the hand developing on a porokeratosis. Despite glandular enlargement the condition had remained healed for three years following roentgen therapy.

#### GROUP B

This is an interesting group of carcinomas, showing as they do such contrast between the two different subgroups. In both group *B'* and group *B''* the condition developed on the basis of some previous neoplasm or wart, one from a congenital growth, usually a nevus or telangiectatic spot, the other from warts or nevi which have appeared later in life. The age contrast between these two types will be considered later. Injury, chronic inflammation and chronic irritation appear to play a rôle here also in leading to malignant changes. Only ten examples of group *B'* have been reported so far as I can ascertain; their almost invariably malignant course warrants placing them in a separate group.

The carcinomas listed under group *B''* practically always develop from cutaneous warts which have been present for several or many years, subjected not only to casual trauma but also to many and varied attempts at removal. Whether or not the agents used to remove these growths stimulate malignancy or whether the growth is slowly malignant from the start cannot be stated. Certainly, a degree of caution should be exercised in treating these usually harmless uncosmetic looking growths. Any unusual changes occurring in a wart should be looked on with suspicion and microscopic examination made. The histories of this type of carcinoma read about the same—viz., von Brunn's<sup>15</sup> case, a woman, aged 73, who had warts on the dorsum of the right hand for many years.\* Following an injury to one of the warts a stubborn ulcer developed which showed no tendency to heal. In six months a large ulcer was produced, and there were enlarged epitrochlear and axillary glands. Removal of the thumb and index finger along with the metacarpals and of the epitrochlear lymph glands (axillary glands not removed because of general condition of the patient) was followed in seven months by local and glandular recurrence. The growth was proved microscopically to be squamous cell carcinoma.

CASE 20.—(Courtesy of Dr. W. C. Wood, Decatur, Ill.) A farmer, aged 91, had a wart on the dorsum of the left thumb over the metacarpophalangeal joint. He was accustomed to prick the wart with his jack knife from time to time. After several years of this attention the wart grew into a large, excavated, malodorous ulcer, for which the patient refused any professional attention. The diagnosis was not confirmed microscopically.

### GROUP C

In forty-four patients (tables 3 and 9) the skin was normal previous to the appearance of the neoplasm, that is, no scars, chronic infection, irritation, or warts. Possibly some may have had etiologic factors, such as those outlined in the previous two groups, but it is certain that the neoplasm may arise *de novo*. The more advanced age of these patients points to senile changes.

CASE 21.—Mr. A., aged 78, Wesley Memorial Hospital, service of Dr. William Schroeder, first entered the hospital in July, 1922, because of an ulcerating mass on the dorsum of the left hand, intense pain in the hand and arm and swellings in the axilla. He said that until three years previously he had noted nothing unusual on the hand, but that about that time a small horny mass, the size of a pinpoint, appeared near the thumb. He took his pocket knife and pricked the swelling, finally making it bleed, which it did profusely. After this treatment the lesion seemed to spread and the edges took on a red, angry look, but no pain was present for some time. The area grew slowly but steadily until a year previous to examination when during a rather severe attack of influenza, which lasted five months, the mass grew fairly rapidly, became elevated and cauliflower-like and bled on the slightest trauma. Sharp shooting pains appeared, which were worse at night, and at first confined to the hand and thumb. Soon, however, a dull, persistent ache developed in the whole arm. A mucopurulent secretion had been coming from the tumor for several months. Two weeks before admission he noted a small, hard nodule in the axilla. The past and family histories were essentially negative. The general physical examination was without any important observations; there was no evidence of any pathologic process in the chest. On the dorsum of the left hand there was a large cauliflower-like mass (fig. 20) with overhanging edges, and raw, red, bleeding surface discharging a foul smelling, mucopurulent secretion. Several small, hard, movable glands were palpable in the axilla. A diagnosis was made of carcinoma of the hand with axillary metastases. On July 24, 1922, the hand was amputated about midway between the elbow and the wrist, and the axillary glands were carefully dissected out. Following this operation the wounds healed smoothly and the pain subsided. The patient was discharged on Aug. 18, 1922. The pathologic specimen examined by Dr. J. P. Simonds showed a squamous cell carcinoma (fig. 21 *A*) with axillary metastases, carcinoma being found in one of the six small glands examined.

Following discharge the patient went home and felt comfortable for some time. The pain practically left him and he gained in weight and strength. Two months later, however, he noted a small firm nodule above the medial epicondyle of the left humerus; it was not painful and grew slowly for several weeks after which it began to grow more rapidly and became tender. There was no corresponding enlargement in the axilla. A month after the gland was noted and about three months after the first operation he again entered the hospital (on Nov. 17, 1922), and the gland was removed. Microscopic examination (fig. 21 *B*) revealed

TABLE 3.—*Tabulation of Twenty-Five Cases of Carcinoma of the Hand*  
A 1: Carcinoma Due to Roentgen Ray or Radium

No.	Age	Sex	Location	Duration of Exposure Before Development of		Treatment for Dermatitis	Treatment for Carcinoma	Lymph Gland Axillary	Result

an infiltration of the lymph gland with squamous cell carcinoma; columns and whorls of cells with many epithelial pearls were seen.

He got along fairly well until June, 1923 (that is, for six or seven months), at which time a small lump appeared on the medial aspect of the left arm. This mass enlarged fairly rapidly and gave rise to a dull aching pain; the patient again entered the hospital (on July 22, 1923). The site of the amputation had healed well, and there was no evidence of recurrence. On the medial aspect of the arm, however, there was a red mass, the size of a "fist," which was firm, circumscribed at the base and fluctuant centrally. Because of the progressive character and proved malignancy of the condition, a scapulohumeral amputation was performed on July 24. The specimen showed a tumor mass about 5 by 4 by 4 inches (12.7 by 10.16 by 10.16 cm), fairly well circumscribed, hard at the base and with a small

Fig. 20 (case 21) —Carcinoma of the hand arising from previously normal skin (Specimen preserved in the Zeit Museum of Pathology, Northwestern University Medical School.)

fluctuant area, the size of a quarter, at the highest point. The old amputation scar was in excellent condition. When opened the fluctuant area was found filled with a light brown caseous material. Microscopic examination (fig 21 C) showed squamous cell carcinoma. No carcinoma was found in the axilla. The post-operative course was smooth, and the patient was discharged on Aug. 12, 1923. He died in November, 1925, at the age of 81. There had been no recurrence of the carcinoma.

CASE 22 —Mr. J. P., aged 58, a butcher, Wesley Memorial Hospital, service of Dr. Van Alstyne, had noted a growth on the dorsum of the right hand for the past two years; it had grown slowly but persistently and had produced no subjective symptoms; no etiologic factor was known. Lately, it had bled freely and easily on slight injury. The mass was excised and the area covered with Thiersch grafts, which healed well in place. The patient was discharged with instructions as to after care and observation. He was not heard from for several years, when on inquiry it was found that he had died from generalized carcinomatosis.

Fig. 21 (case 21).—Photomicrographs of carcinoma removed at various times from the case in figure 20. *A*, section from primary site; *B*, epitrochlear gland recurrence; *C*, recurrence in the skin of the arm.

## GROUP D

This group includes cases not classed in any other group. Except for the age, sex and distribution, little is to be learned from an etiologic standpoint.

CASE 23.—Mrs. M. G., aged 79, a housewife, Wesley Memorial Hospital, service of Dr. Horn, entered the hospital on June 16, 1913, complaining of a nodular mass, the size of a hazelnut, on the dorsum of the left hand. It had been present for two years, and no inciting cause could be discovered from the history. During the two weeks previous to admission, a sudden accession of growth was noted. Examination revealed a nodule, the size of a hazelnut, on the dorsum of the left hand. No record was made as to involvement of the lymph glands. The tumor was removed from the hand under gas anesthesia. The microscopic section showed a typical squamous cell carcinoma of a moderately malignant type, with large epithelial pearls and not a great deal of stroma. Masses of round cell infiltration were seen throughout. No word has been received from the patient since the operation.

CASE 24.—Mr. J. C., Wesley Memorial Hospital, service of Dr. M. Goldstine, was admitted to the hospital, on April 18, 1923, for treatment for an ulcerating mass, the size of a walnut, on the dorsum of the right hand. It had been present for two years, arising from no apparent cause. Several roentgen treatments had been given without success. Radium was applied for twenty-four hours. (There was no record of the amount of the dose.) Four years and five months later his daughter wrote that, "there has been no recurrence or any symptoms of further trouble."

CASE 25.—M. R., aged 77, a farmer, Wesley Memorial Hospital, service of Dr. H. M. Richter, had noted a nodule, the size of a pea, on the left side of the face and a similar one on the right forearm for about two or three years. They were both removed. Microscopic section showed the lesion on the cheek to be a basal cell carcinoma and the lesion on the arm a squamous cell carcinoma.

## COMMENT

## ETIOLOGY: AGE

As with neoplasms in general, the average age of patients with carcinoma of the hand is fairly high. Thus, in 239 instances (tables 4 and 5) in which the age is noted the general average is 59 years, 58.4 years for the males and 60.1 years for the females. In each group the males and females average about the same. In group *A*, with some specific factor as stimulative agent, the average is only 54.4 years or 4.6 years lower than the average for the whole series, 9.9 years lower than the average for *B*", 7.5 years lower than the average for *C*, and only 1.1 years higher than the average for *B'* (53.3 years). These averages would suggest that although age is a factor the other conditions do play a definite rôle. The age contrast is further emphasized in table 4, in which the cases are grouped according to decades and etiology. Of the 239 cases there are 212 in the decades from forty to seventy-nine, with only nineteen below the age of 40, and eight over the age of 79. The decade 40 to 49 is made up largely (twenty-four of thirty-seven cases) by the large contingent from group *A*. Also, of the twenty cases

under 40, twelve come from group *A* and six from group *D*, while groups *B'* and *C* have only one case each. In group *B'* only ten cases were found, in nine of which age and sex are given, and these, as noted before, average 53.3 years of age; the youngest patient in this group is 43 and the oldest, 79. I cannot substantiate for the carcinomas of the hand the statement so often made for carcinomas of the extremity, viz., that those developing on some congenital neoplasm occur at a younger age (from 30 to 40) than any others. The majority of the younger patients are in the group with some irritative etiology. Thus, there is Stahr's<sup>32</sup> case of shoemaker's carcinoma in a boy of 17, Carnett's<sup>26</sup> recently reported case in a young man of 24 following injury from the spike of a baseball shoe, and case 17 of a precarcinomatous ulcer from an alkali burn in a boy of 18. Roentgen carcinoma, in common with carcinomas of irritative or traumatic etiology, occurs in

younger persons (from 30 to 50) probably because the incidence of exposure is higher among young men. The tendency for malignant changes to develop late in roentgen dermatitis, however, explains the not infrequent occurrence of carcinoma in older patients.

#### SEX

Males outnumber the females almost 2:1, 154 to eighty-eight or 65 per cent males to 35 per cent females. The ratio of males to females is slightly higher (67:31) in group *A* than in the other groups. Roentgen carcinoma of the hand occurs almost exclusively in males.

#### LOCATION

The striking predominance with which these carcinomas attack the dorsum of the hand and their rarity on the palm or on the volar surfaces of the fingers have given rise to considerable speculation (table 5). Sixteen cases (5.9 per cent) were found of carcinoma on the volar surface of the hand and fingers. Nine of these are from group *A*,

three from group *C*, and four from group *D*. As the latter are without any data as to etiologic factor the importance of trauma in causing palmar carcinoma is evidently great. The marked histologic differences between palmar skin and the skin over the dorsum of the hand, particularly the thick protective stratum corneum, explain to some extent the rarity of palmar carcinoma. One would expect the thick horny skin to respond to chronic irritation and scars with a minimum of carcinomatous change. In 144 instances in which the sides of the body were distinguished, the right hand predominated (eighty-nine to fifty-five). This is also suggestive of a traumatic factor. When the neoplasms arise from apparently normal skin, the sides are about equal; of twenty-five in which data are given there are twelve right and thirteen left. The roentgen carcinoma is always on the dorsum of the hand, predominately more often on the left than on the right, so that when one speaks of the "x-ray hand" it is the "left hand of an old operator" that is called to mind.

#### SYMPTOMS AND CLINICAL COURSE

That the carcinomas arising on the hand have a long chronic course is attested by the fact that the duration of symptoms, namely, the presence of an ulcer, averages from two to three years before the patient seeks advice, and even then it is not too late, as a rule, to cure the condition. Among the patients in group *A*, the duration averaged 2.6 years; group *B'*, 0.95 years; *B''*, 2.4 years; *C*, 1.9 years, and *D*, 2.9 years. One cannot say, of course, that a malignant condition has been present all the time since the patient noted the first changes; however, it does appear logical to assume that the condition was malignant from the start. Early biopsy specimens may prove puzzling, but this does not signify that the specimen in question is not malignant. The study of any cutaneous carcinoma convinces one that a great deal depends on the number of sections studied.

Cumston<sup>18</sup> and several of the French authors whose theses I have reviewed divide the clinical course into two stages, the preulcerative and the ulcerative. Obviously, when a malignant condition develops on the basis of an ulcer this subdivision cannot be made. In the preulcerative stage a small tumor appears usually on the dorsum of the hand over a metacarpophalangeal joint. It may start as an induration in the skin or as a small scaling nodule intimately incorporated in the skin from which it is not definitely demarcated. The skin over the nodule may be thin, dry and parchment-like, or it may be hypertrophic with numerous gray or rosy-red papillae surrounded by dilated capillaries. The nodule continues to develop, giving rise to few, or no, subjective symptoms, unless it is a slight itching. It is only a matter of time until the nodule breaks down, either by the formation of crevices which refuse to heal or as the scale is removed a reddish shining surface is left behind which slowly breaks down. Instead of a definite ulcer

the carcinoma may form an exuberant cauliflower-like mass, the surface of which is irregular, granular and ulcerous.

As the ulcer or cauliflower mass grows, it encroaches more and more on the surrounding skin, the floor becomes granulating, pinkish or

grayish and discharges a seropurulent or even sanguineous secretion which becomes malodorous due to saprophytic infection and gangrenous changes. Hemorrhage, as in case 18, may be extremely severe. The growth invades not only surrounding skin but eventually also the deeper

structures, muscles, tendons, bone, etc. The deep invasion as a rule is late, and extensive changes may be present in the skin before there is much local invasion. This must not be taken to indicate a benign character, as the tumor has all the malignant tendencies of the most malignant tumors except rapidity of growth.

The involvement of lymph glands is frequent but occurs late. In 122 cases in which the lymph glands are noted (table 6), they were enlarged in sixty-two cases (51 per cent) and not enlarged in sixty (49 per cent). Of the cases in which the lymph glands were involved, in thirty-four (55 per cent) the axillary glands alone were affected; in twenty-one (34 per cent) the axillary and epitrochlear glands were both affected, and in seven (11 per cent) the epitrochlears alone were affected. The axillary glands were involved, therefore, fifty-five times in sixty-two cases with glandular involvement. The duration of the condition in those cases with and without enlarged glands is about equal, i.e., 29.8 and 32.6 months, respectively. I do not know, of course, how long glands were present before they were recognized, nor do I know that the enlarged glands were due to carcinoma, since the ulcers are always infected and enlargement may well be inflammatory. I can safely say, however, that glandular involvement occurs late, often after two or three years or longer.

The destructive action of the growth and the presence of infection are accountable for the terminal symptoms. Pain may be extremely severe, not only from local pressure but also from direct invasion of the nerve trunks or enlargement of the axillary glands involving the brachial plexus. Destruction of the muscles and tendons or inflammatory changes lead to marked functional loss in the later stages, and toxic symptoms develop from absorption of products from the infected area. Generalized metastases, usually to the lungs and liver, occur late.

#### PATHOLOGIC CHANGES

The microscopic picture is that of carcinoma of the skin elsewhere. So far as I can ascertain they are almost all squamous cell carcinomas, though recently Iwamoto<sup>37</sup> reported one of basal cell character occurring in a scar on the foot, and Hazen and Whitmore<sup>36</sup> noted three basal cell carcinomas of the hand.<sup>38</sup> The carcinomas vary in the amount of stroma in proportion to the epithelial elements. Inflammatory infiltration is present in variable degrees in all. Mitoses are frequently

37. Iwamoto, M.: Beiträge zur Kenntnis des Narbenkarzinoms, Bitt. ü. allg. Path. u. path. Anat. 2:573, 1926.

38. The Subungual Melanoma or Melanotic Whitlow of Hutchinson (Specht, Karl: Ueber das primäre subunguale Melanoblastom, Deutsche Ztschr. f. Chir. 202:390, 1927. Womack, Nathan A.: Subungual Melanoma, Arch. Surg. 15:667 [Nov.] 1927) may or may not be carcinomatous. These tumors have not been included in this report.

observed. Tixier<sup>39</sup> and Lapeyre<sup>40</sup> reported instances of carcinoma of the hand in which both tuberculous tissue and carcinomatous tissue were present. Tixier's case developed on the basis of an old lupus; Lapeyre's from a burn. Spontaneous healing in some parts of the ulcer, at times practically covering the area with thin, poorly vascularized epithelium (Kaufmann,<sup>41</sup> Corlette and Inglis<sup>42</sup>), is followed by renewed growth. When the carcinoma has invaded bone, or in cases in which a carcinoma has developed from a fistulous tract going down to the bone (Erdheim<sup>43</sup>), tiny spicules of the bone destroyed by the invasion may be found in the epithelial pearls of the tumors. The interesting manner in which fascial planes offer some resistance to these carcinomas is well illustrated in case 18.

The lesions may be multiple on the same hand or both hands or on the hand and some other part of the body. Von Brunn<sup>15</sup> noted eight cases in which carcinoma of the extremity occurred associated with carcinoma of some other structure, and the cases reported (18 and 25) are also illustrative, especially case 18 in which no less than four carcinomas were present. Although C. Kaufmann<sup>44</sup> suggested direct inoculation from hand into eyelid in a case reported by him, this explanation is difficult to accept. Parker<sup>33</sup> reported a carcinoma occurring on the face eight years after two fingers were amputated for carcinoma of the hand. This type of multiplicity is interesting, illustrating perhaps individual tendencies to the development of carcinoma; however, more important clinically are those which occur multiply on the same hand, illustrated so well by the roentgen carcinomas.

The diagnosis depends a good deal on whether the condition is considered at all. Probably the most confusion arises between carcinomas and chronic infectious processes with massive granulomatous changes; such as the cases reported by Perkins<sup>45</sup> and Carnett.<sup>26</sup> Microscopic study may not show until later the true character of the condition,<sup>46</sup> and

46. A. E. Hertzler recently reported three tumors of the forearm, which he called chromomas and which he believed came from the chromatophores. These he compared to the carcinoma reported by Carnett. (*Chromoma of the Forearm*, Ann. Surg. **87**:99, 1928.)

even then may show its true characteristics only in the metastatic nodules. Syphilis and tuberculosis must be considered when one is confronted with a stubborn tumor of the hand. The history of long continued exposure to the roentgen rays and the presence of a hyperkeratosis are suggestive.

The prognosis for carcinoma of the hand is relatively favorable, though this must be understood to mean that it is the slow course rather than the lack of invasive power which makes the lesion less to be feared. The tendency for multiple growth must also be kept in mind. In 225 cases (exclusive of roentgen carcinoma) in which the type of operative procedure is given, 113 of the patients were treated by radical means, ninety-five by conservative means, while in seventeen conservative measures were first tried and later, with a recurrence, more radical steps were taken. Briefly, the results are recorded as satisfactory in eighty-seven (five year cures, twenty-eight; from three to five year cures, twelve; from one to three year cures, seventeen; cures of less than one year, seven; no duration given, twenty-three), failure in thirty-eight, death from causes other than carcinoma in nine, postoperative course not given in ninety-one. If these ninety-one cases are taken from the 225, there is a total of 134 on which there is a fair amount of information. Thus, it is seen in table 7 that regardless of the type of treatment or the type of carcinoma the general percentage of cures is 65 per cent. Except for basal cell carcinoma, as it occurs on the face, I doubt if any other carcinoma can be given such a favorable prognosis. Schreiner<sup>47</sup> presented some elaborate statistical studies on the prognosis for malignant growths and showed comparatively favorable prognosis (for cancer) of many types, but in considering my figures, it must be remembered that all stages of development of the carcinomas are included among the figures given, the early and the late, and there is still a favorable outcome in 65 per cent.

The difference in prognosis as shown by table 7 for the different groups is instructive. The best prognosis seems to be given in patients in group *D* though here the paucity of data somewhat vitiates the results. Although twenty of a total of twenty-four were reported as cured, seven, or nearly 30 per cent, were cures of unknown duration. If, as in the lower row of table 7, one subtracts the percentage of cures of unknown duration, one has left comparable figures for the different groups, and these are seen to compare favorably. They all (with the exception of group *B'*) average about 50 per cent cures of known duration.

Group *B'* not only is the most unfavorable type of carcinoma to occur on the hand but is also evidently one of the most malignant of any

type of carcinoma. Of ten cases the records are complete in six; of these, five died from the carcinoma and one from some other condition. Group B" has also a rather unfavorable prognosis in comparison to the other groups; thus, there are 40.5 per cent known failures and only 52 per cent cures reported for twenty-seven patients, despite the fact that there were 29.6 per cent cures of five years or over recorded.

So far as the statistics for the different groups are concerned, I can say that the carcinomas arising from scars or as the result of trauma or infection and those arising from the intact skin have the most favorable prognosis, while those arising from some previous growth of congenital origin have the worst.

The prognosis varies somewhat with the type of operative treatment, though as it appears more favorable with conservative than with radical measures I can conclude only that the more radically treated patients

TABLE 8—*Contrasting the Results of Radical and Conservative Methods of Treatment in 122 Cases of Carcinoma of the Hand (Exclusive of Roentgen Carcinoma) in Which the History Subsequent to Treatment Has Been Given*

	21 (33.8%)	13 (21.3%)
	4 (6.5%)	3 (5.0%)

were probably more advanced and had inherently poorer prognoses. Table 8 shows the comparative results of radical and conservative procedures in all types of cases; there are sixty-two and sixty, respectively, completely recorded cases in the groups. The radical procedures gave 59.5 per cent cures, and the conservative, 73.5 per cent. Other comparisons may be made directly on the table. Much value cannot be attached to these comparative statistics, except so far as they emphasize the efficacy of conservative treatment when the condition is not far advanced.

It does not appear that the carcinomas of long duration have a more unfavorable prognosis than those of shorter duration. Of course, other factors enter in here, such as the degrees of malignancy of the condition and the inability to judge the onset of malignant changes.

The presence of glandular involvement appears to be a decided factor in determining the prognosis (table 6). Despite the fact that it has been said that early involvement is often inflammatory and not carcinomatous it would appear to me that often the failure to note glandular metastases depends on searching through insufficient material. Of thirty-seven cases in which the glands were affected, and the course

subsequent to operation was known, the treatment was a failure in twenty-one, or 57 per cent, and successful in fourteen, or slightly less than 38 per cent. Without involvement of the lymph glands the results are favorable in 71.3 per cent and failures in 25.7 per cent.

#### TREATMENT

The relatively favorable prognosis for carcinoma of the hand should not put one off one's guard. Although conservative measures result in as many cures as the more radical procedures, the distinction between conservative and radical procedures in this instance is more apparent than real in that the underlying principle is the same, i.e., removal of all carcinomatous tissue. Obviously, if this is small in amount and no invasion is present, as determined by frozen section, a simple excision is all that is required; with a large invasive mass more tissue must be removed to accomplish the same result. As far as the carcinoma itself is concerned, the operation must always be radical.

It is logical to divide the treatment for carcinomas of the hand into two types, depending on the type of carcinoma. These two types may be called localized carcinoma, as exemplified by those tumors arising from scars or following infection and trauma, from the unchanged skin, etc., and generalized carcinoma, such as is well illustrated in the case of the roentgen and radium dermatitis. While the rationale of treatment is the same in each case the *modus operandi* differs, and for sake of emphasis I believe that the two types should be discussed separately. In the case of the isolated carcinoma the rest of the hand presents no lesions which are or may become malignant, except by direct extension from the original growth. In the case of the multiple type, however, not only may there be several carcinomas present at the same time, but there are frequently precarcinomatous lesions which, regardless of the removal of the actual carcinomas, can develop into malignant tumors.

Despite the favorable results of irradiation treatment in several of the cases here reported and the excellent results of Hazen and Whitmore<sup>40</sup> with the roentgen rays, not only in cases of basal cell carcinoma but also in cases of squamous cell carcinoma, I feel that the use of these agents is not indicated in this condition. While it appears that the danger of roentgen and radium dermatitis is not great when actual treatment is received, I feel that in operative cases surgical intervention is the method of choice. In the case of irradiation carcinomas too much cannot be said against the use of other irradiation (McArthur,<sup>48</sup> Porter<sup>49</sup>) to cure the effects of the first one.

48. McArthur, L. L.: *Injurious Influence of the Use of the Ultraviolet Ray on Old X-Ray Burns*, Surg. Gynec. Obst. **41**:97, 1925.

49. Porter, C. A.: *The Surgical Treatment of Roentgen-Ray Lesions*, Am. J. Roentgenol. **13**:31, 1925.

In the case of isolated carcinomas the extent of the surgical excision depends on the extent of involvement and the condition of the axillary and epitrochlear lymph nodes. Each case is individual. Frozen section at the time of operation is the only exact method by which one may judge the amount of tissue to be removed. In general, the superficial carcinomas involving the dorsum of the hand may be widely excised without the necessity of removing portions of tendons or bones. Frequently, a considerable area of skin is removed by the operation and due to the wide separation the edges of the skin at either side cannot be brought together; here it becomes necessary to graft skin, which is best done by means of pedunculated flaps taken from the abdomen or, as discussed later, from the thigh as pocket grafts. While it would be preferable for one to raise the flaps and be assured of their vitality before applying them, the exigencies of the case do not permit the three weeks' delay necessary for this precaution. Usually, however, a well planned flap will survive. Thiersch grafts and free full thickness grafts can be used; however, because of the need of great flexibility of the skin on the dorsum they are not so suitable as pedunculated grafts with subcutaneous fat.

In case of deep ulcers and large cauliflower growths it is possible at times to preserve portions of the hand, such as a thumb and finger, and so leave the patient with a useful hand.

Carcinomas of the nail-bed appear to be especially malignant, and in view of the possibility of melanoma should be treated by amputation of the finger.

The presence of glandular enlargement calls for thorough axillary or epitrochlear dissection or both. Despite the frequent statement that such enlargements are inflammatory in a good percentage of cases, I am inclined to look on them all as potentially malignant. The distinctly more serious prognosis rendered by the glandular invasion warrants their careful dissection if there is any suggestion that they are enlarged. If the carcinoma is of such extent as to require extensive operation for removal, such as amputation of the hand in which deep invasion has occurred, it is well to dissect the axilla regardless of the glandular enlargement. Routine axillary dissection is by no means necessary, owing to the slow growth of the carcinoma; but it is necessary with a process of two or more years' duration. The chances are that there may be an invasion of the lymph glands, and the possibility must be thought of carefully.

In the case of roentgen and radium dermatitis with carcinoma, the problem of removal is a more difficult one. The process is usually more extensive than it appears at first glance, because of the presence of changes in the subcutaneous tissues and blood vessels. The "tendency is too conservative" (Porter) and many involved areas are left behind,

necessitating future removal. It seems to me that the key to the whole question is found in the histories of the cases of roentgen carcinoma. It should be remembered that numerous areas are involved, the process is generalized over the whole dorsum of the hand, as evidenced by the presence of keratoses and telangiectases, and not one area but from two to twenty or more spots may develop into carcinoma. The fact that recurrence, if it occurs, is usually in some other spot than the one on which operation is performed is a comfort and should lead to the correct therapeutics. All involved tissues should be removed at one time preferably, whether clinically malignant or not. The keratoses may be coagulated or desiccated (Pfahler<sup>50</sup> has successfully removed hundreds from his own hand by electrocoagulation), though here most surgeons are inclined to follow Porter and advise excision in preference. Ulcers and larger areas of involvement must be excised, and fingers, if deeply invaded, are usually best amputated.

The necessity of removing a considerable amount of skin from the dorsum of the fingers and hand entails some method of plastic covering of the denuded areas. Thiersch grafts or free full thickness grafts may be applicable in cases in which only small areas require covering. If large areas, such as the backs of several fingers, are denuded, however, a pedunculated or pocket graft is the method of choice. Since the skin of the thigh is more nearly like that of the back of the hand, this area is preferable to the abdomen. Case 8 and figure 7 illustrate the method of covering the backs of several fingers by means of a pocket graft from the thigh.

The question of removing the glands in the case of roentgen carcinoma is a perplexing one. Here the opinion is somewhat divided. Many investigators contend that enlarged glands are frequently inflammatory and not carcinomatous. If, however, glandular enlargement is present, the wisest course appears to be that of removal. If they are not enlarged, it is safe to leave them since there is always the possibility that they act as valuable filters of the lymph stream and may remove carcinoma cells from it. If they have been removed it is important to watch the patient carefully for the development of carcinoma on new spots as any protective action which these glands may exert is gone (Porter).

The use of any type of irritant on a hand with roentgen carcinoma is absolutely contraindicated. Above all, the further irradiation of the hand is to be avoided, particularly with the present popular ultraviolet ray. McArthur<sup>48</sup> especially deplored the use of the ultraviolet ray in old

burns from the roentgen ray, despite the contention that the roentgen ray and the violet ray are complementary. His own case report and the one reported in this paper (case 5) illustrate the dangers of this type of treatment.<sup>51</sup> Radium, while advised strongly for these cases (F. H. Williams<sup>52</sup>), appears to me to entail too much risk.

### SUMMARY

Carcinoma of the hand is a condition of the advanced years, occurs more frequently in the male than in the female and (excepting roentgen carcinoma) more often on the right than on the left hand. The majority of carcinomas are located on the dorsum of the hand. It is convenient to divide these carcinomas into four large groups, depending on the etiologic factors present. In group *A* are those arising from irritation, trauma, scars, irradiation, etc. I have purposely made a separate group (*A* 1) of the irradiation carcinomas because of their large number and importance. In group *B* are those arising from some previous growth—*B'* congenital and *B''* acquired; in group *C* are those appearing on the previously unchanged skin, while in group *D* are those cases in which data are too meager to allow classification. If one excludes roentgen and radium carcinomas, group *A* makes up two fifths, and groups *B*, *C* and *D* each one fifth of all reported cases of carcinoma of the hand. Irradiation would probably account for 30 per cent of these carcinomas. All but a very few of the carcinomas are squamous cell in type and therefore serious.

Diagnosis may be difficult even with microscopic section, and the clinical course and history are of value in reaching a decision. Many granulomatous lesions appear to be in reality carcinoma in which frozen section is negative for malignancy. The prognosis is in general favorable for the cases in groups *A* and *C*, fair in group *B''* and very poor in group *B'*. In the case of roentgen carcinoma the prognosis is good, providing all involved tissue, whether carcinomatous or not, is removed. Conservative measures are usually successful if promptly carried out, and radical surgical treatment is needed only in neglected cases, with the exception of cases in group *B'* in which radical surgical intervention is advisable from the start. In the case of carcinoma arising from roentgen dermatitis, in which multiple areas of keratosis are present, it is imperative that all keratotic spots are excised regardless of their extent.

---

# ENTEROSTOMY IN THE TREATMENT OF GENERAL PERITONITIS\*

THOMAS G. ORR, M.D.

AND

RUSSELL L. HADEN, M.D.

KANSAS CITY, KAN.

The subject of intestinal drainage in intestinal obstruction and peritonitis has been much discussed since the work of Victor Bonney<sup>1</sup> in 1910, in which he emphasized the importance of this method of treatment. Summers,<sup>2</sup> MacKinnon,<sup>3</sup> C. H. Mayo,<sup>4</sup> Taylor,<sup>5</sup> Walker,<sup>6</sup> Wilkie,<sup>7</sup> Long<sup>8</sup> and Lee and Downs<sup>9</sup> have all written of the value of high jejunostomy or enterostomy in the treatment for acute intestinal obstruction. MacKinnon is so enthusiastic concerning this method of treatment that he uses high jejunostomy in treating patients with other postoperative conditions in which abdominal distention or paralytic ileus are likely to occur; he terms it "complimental jejunostomy." The report of Van Beuren and Smith<sup>10</sup> and recent experimental work have been a signal to stop and consider just what results are generally being obtained with drainage of the intestine in obstructions. Van Beuren and Smith stated that they were not able to discover definite, incontrovertible proof that enterostomy had lowered the mortality rate in cases of acute ileus. We have recently shown that drainage of the upper jejunum in dogs will cause death in all cases in from two to five days, with changes in the blood chemistry similar to those found in high intestinal obstruction.<sup>11</sup> Walters, Kilgore and Bollman<sup>12</sup> obtained similar results in experimental drainage of the duodenum. Drainage of the lower ileum does not cause such disturbance. Dogs will live several weeks with drainage of the ileum 6 inches (15.24 cm.) above the cecum.

Whether or not drainage of the upper intestine clinically has any such dangerous consequences remains to be determined by future observations. Heidenhain<sup>13</sup> warns that death from inanition may quickly result if a high loop of the small intestine is drained.

An interesting opinion as to the cause of death in general peritonitis has been recently expressed by Pringle<sup>14</sup> of Dublin. He expressed the belief that death in acute septic peritonitis is not, in most cases, due to absorption of the products of the suppurative inflammation of the peritoneum, but to intestinal toxemia secondary to paresis of the inflamed intestine. In this belief he was supported by Handley,<sup>15</sup> who stated that the "proximate cause of death in suppurative peritonitis is intestinal obstruction. The fatal dose of poison is usually absorbed from the intestine above an obstruction and not from the peritoneal cavity." He further stated that if peritonitis does not produce obstruction, the condition may become universal without being fatal.

In connection with the aforementioned statement we may refer to the opinion of Gatch, Trusler, and Ayers<sup>16</sup> who believe that death in cases of high intestinal obstruction is due to hypochloremia and dehydration and not to a toxemia arising from the contents of the obstructed intestine. This belief is concurred in by Wangensteen and Chunn.<sup>17</sup> Bacon, Anslow and Eppler<sup>18</sup> concluded that death from intestinal obstruction is, in the absence of complications, due to toxemia from the disintegration of protein which occurs after severe loss of water. They expressed the belief that it is the most common clinical example of death from thirst. If one accepts the statement that the cause of death in general peritonitis is due to intestinal obstruction, one might further conclude that the cause of death is due to dehydration and hypochloremia.

It seems logical to believe that if bacteria are absorbed from the infected peritoneum, toxins elaborated by such bacteria would also be absorbed. David and Sparks<sup>19</sup> have recently shown that colon bacilli will pass from the normal peritoneum into both the thoracic duct and directly into the blood stream. The presence of a plastic peritoneal exudate retards this passage, while a transudate does not. These authors believe that the severe toxemia associated with general peritonitis must be caused in some degree by absorption of bacterial toxins from the peritoneum. To prove this they have shown that diphtheria toxin is

absorbed by the normal peritoneum directly into both the lymphatics and the blood stream. Peritonitis with a plastic exudate retards or prevents this absorption, and transudates favor the passage of the toxin from the peritoneum. With these experimental results in mind, we should hesitate to ascribe death in general peritonitis wholly to the toxins developed in the obstructed bowel. It is obvious that this cannot be true if dehydration and hypochloremia are the cause of death in acute ileus, as suggested by Gatch and others.

Sampson Handley<sup>15</sup> described a condition which he believed exists in most cases of peritonitis in which a section of both the large and the small intestines are obstructed by peritonitis of the lower part of the abdomen. This he has called "ileus duplex." To effect drainage of this double bowel obstruction he has advocated a jejunocolostomy between a loop of the jejunum and transverse colon in addition to a cecostomy. He reported four cases of peritonitis following appendicitis in which this treatment was used; these cases appeared hopeless to him after he had tried the customary treatment with pelvic drainage, Fowler's position, saline infusion, eserine, pituitary and purgatives. After his operation, all patients showed a subsidence of distention, cessation of vomiting and return of natural evacuations per anum in forty-eight hours.

Pringle<sup>14</sup> reported nine cases of peritonitis in which treatment consisted of jejunostomy, with seven recoveries. Some of his cases he considered hopeless when the operation was done. He urged the use of this method in cases of "diffuse general suppurative peritonitis of the lower abdomen associated with appendicitis, tubal disease, and other septic conditions in the pelvis—the cases in which the intestines in the pelvis are acutely inflamed and the infection is already spreading upwards into the abdomen proper, so that, immediately on opening the abdomen, pus is seen lying between the congested coils of small intestine without limiting adhesions and, if a hand is passed down into the pelvis, a regular well of pus is found in the pouch of Douglas."

In May, 1925, Hübener<sup>20</sup> discussed secondary enterostomy in peritonitis and ileus, reviewing the German literature up to that date. He found that opinions are divided in regard to the cause of death in peritonitis and ileus. He further found that there was disagreement concerning the value and indications for secondary enterostomy. Hübener was of the opinion that enterostomy should be done in peritonitis after conservative means have failed to reestablish peristalsis. He reported thirty-two cases in which enterostomy was done as a secondary operation, in sixteen of which there was some degree of peritonitis. Of this total number of patients, eight were cured. He concluded that secondary enterostomy is often a determining factor

20. Hübener, Hans: Beitr. z. klin. Chir. 134:93, 1925.

and never does harm, and he used it in all cases in which operation and postoperative management did not cause a return of gut function of the intestine. The enterostomy is done, if possible, before any decided paralysis of the intestine results.

Roeder<sup>21</sup> emphasized the importance of acute inflammatory obstruction of the terminal ileum as a result of appendicitis and peritonitis and recommended as treatment early ileosigmoidostomy to drain the dilated ileum. Of his twenty-one patients so treated, twenty recovered.

Our personal experience in the treatment of patients who have general peritonitis with enterostomy has been limited to five cases. These cases represent the acute general diffuse type of peritonitis and the type designated as acute inflammatory obstruction of the ileum or peritonitis of the lower part of the abdomen. The origin of the peritonitis in all cases was acute appendicitis.

#### REPORT OF CASES

CASE 1.—J. G. K., a man, aged 48, was admitted to St. Lukes Hospital on April 4, 1925, in the service of Dr. John G. Hayden. The onset of his illness began three days before with acute abdominal pain and vomiting. When admitted to the hospital, his abdomen was much distended, and general abdominal tenderness and rigidity were marked. Operation revealed a gangrenous appendix with general peritonitis extending into the upper part of the abdomen. The pelvis was drained, and an enterostomy was done in a presenting coil of small bowel. There was little drainage from the enterostomy tube. The general condition of the patient did not improve, and he died twenty-four hours later.

CASE 2.—A. G. L., a man, aged 47, was a patient in the Bell Memorial Hospital from Dec. 12 to 20, 1925. Two days before admission, his illness began with acute pain in the lower part of the back. Later there was generalized abdominal pain. A diagnosis of appendicitis of the pelvic type was made after admission to the hospital. There was much abdominal distention and prostration. An appendical abscess was drained from deep in the pelvis. Free fluid was found in the abdomen. Little improvement followed this operation. An enterostomy through the upper left rectus muscle was made twenty-four hours after the abscess was drained. The intestines were found covered with fibrin. Drainage from the tube was slight. There was no improvement in his general condition, and he died four days following the enterostomy. Autopsy showed peritonitis throughout the entire abdomen.

CASE 3.—M. J. B., a man, aged 48, was admitted to St. Mary's Hospital on July 21, 1928. His illness began the evening before with a pain in the lower part of the abdomen, which grew worse during the next day. He had some vomiting and marked diarrhea with ten stools the first day of the disease. On admission to the hospital, there was tenderness of the abdomen. There was slight distention. Vomiting, diarrhea and pain abated, and he seemed to improve for several days. The leukocyte count dropped from 12,000 to 3,200. On the sixth day of his illness, he had a severe pain in the abdomen, with a rapid rise in the pulse rate and temperature. It was then realized that a general peritonitis had developed. An enterostomy was done by the Witzel method in the first portion of the small intestine presenting through an incision in the right rectus muscle. The abdomen contained turbid fluid. There was no improvement following this operation, and

21. Roeder, C. A.: *Ann. Surg.* 87:867, 1928.

death resulted fourteen hours later. Autopsy revealed an extensive general peritonitis.

CASE 4.—J. D., a girl, aged 12, was admitted to the Bell Memorial Hospital with a history of acute abdominal pain and vomiting which began three days before presentation. Examination revealed typical symptoms of acute appendicitis. An appendix with beginning gangrene and peritonitis was found at operation. The wound was drained. About ten days after operation, symptoms of intestinal obstruction developed. Enterostomy was done three days later through an incision in the left rectus muscle. Drainage from the enterostomy tube was good. The third day following enterostomy the bowels moved, and the patient was given a soft diet. Drainage tube was removed on the tenth day. Recovery was complete. The diagnosis was peritonitis of the lower part of the abdomen and obstruction of the small bowel.

CASE 5.—A. L., a man, aged 24, was operated on for a gangrenous appendix on Aug. 22, 1928, at St. Mary's Hospital. He developed peritonitis, and convalesced slowly. At the end of two and a half weeks his temperature was normal, and he was able to eat a regular diet. Four weeks after operation, he developed some pain in his abdomen. This grew worse, and in three days he had definite evidence of peritonitis and intestinal obstruction with pain, vomiting, visible peristalsis, a pulse rate of 116, a temperature of 102.8 F. and slight distention. An enterostomy was done by the Witzel method through an incision in the upper left rectus muscle, using the first loop of small intestine that presented. There was free turbid fluid in the abdomen, and the intestines were distended and injected. Copious drainage of yellowish-brown liquid from the bowel began at once from the enterostomy tube. At the end of three days, the bowels moved spontaneously. The drain was removed in six days, and the wound closed promptly. He made a complete recovery, and left the hospital in good condition. The diagnosis was obstruction of the small bowel due to peritonitis of the lower part of the abdomen.

We have recently made some experimental studies which seem to have a bearing on this subject. Experimental peritonitis has been produced in dogs by ligating the appendix with tape.<sup>22</sup> The changes in the blood chemistry in these animals simulate those found in acute intestinal obstruction. There is an increase in the nonprotein nitrogen and urea nitrogen and a decrease in the chlorides (chart 1). We have also found such changes in a number of clinical cases (chart 2). Since these chemical changes are similar to those found in acute obstruction of the upper intestinal tract it might be thought that they lend some support to the opinions already expressed that the cause of death in general peritonitis is due, not to peritoneal infection, but to toxemia from the obstructed bowel. To estimate the value of enterostomy experimentally in the treatment of patients with general peritonitis, the divided ileum 6 inches (15.24 cm.) above the cecum was sutured to the skin in a series of dogs at the same time the appendix was ligated to produce peritonitis.<sup>23</sup> This operation did not prolong life. When a similar series of dogs was treated with enterostomy in addition to a 1 per cent solution of sodium chloride hypodermically, the duration of life after the ligation of the

23. Orr, T. G., and Haden, R. L.: to be published in *J. Exper. Med.*

appendix was tripled. Table 2 shows the results of these three series of experiments.

Simple low enterostomy does not prevent the typical changes in the blood which occurs in general peritonitis (chart 2). The administration of a solution of sodium chloride does prevent these typical chemical changes when given in sufficient quantity (chart 3).

# COMMENT

In estimating the value of enterostomy in the treatment of patients with peritonitis, two factors should be taken into consideration: the

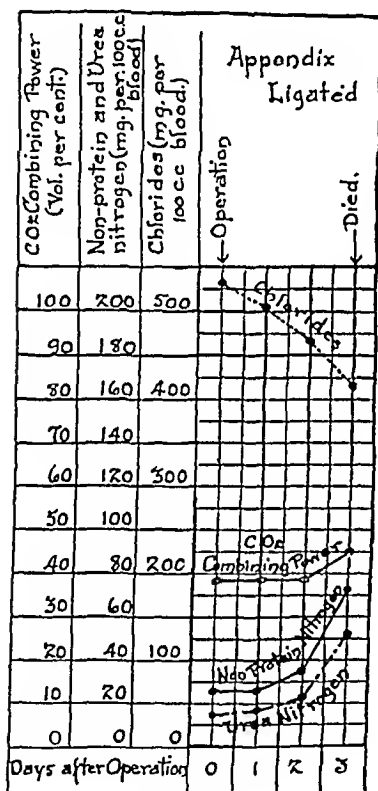

Chart 1

Chart 2

Chart 1.—Typical changes observed in the blood chemistry of experimental general peritonitis.

Chart 2.—Changes in the blood chemistry of experimental general peritonitis are not altered by low enterostomy.

extent of the peritonitis and its duration. If the entire abdominal cavity is involved in the infection with free fluid and if much damage is done to the tonicity of the wall of the bowel, it is probable that enterostomy will be of little avail. If the peritonitis is chiefly in the lower part of the abdomen with obstructive symptoms associated with spasmodic

cramps or visible peristalsis as in cases 4 and 5, enterostomy will undoubtedly result in much benefit. Enterostomy in cases of peritonitis of the lower part of the abdomen with obstructive symptoms is a much safer and saner procedure than abdominal exploration with its associated trauma and spread of disease.

It is our opinion that when any doubt exists regarding the value of enterostomy, it should be done. If proper technic is followed, the operation has little risk of shock or infection. One cannot depend on clinical examination to estimate the viability of the intestine. If the intestines possess any remaining peristaltic activity, an enterostomy may be the means of saving the patient's life. It should be done under local

TABLE 1.—*Single Examinations of the Blood in Clinical Cases of Proved General Peritonitis*

Name	Blood, Amount per 100 Cc.			Carbon Dioxide Combining Power, per Cent by Volume	Cause

TABLE 2.—*Average Duration of Life in Experimental General Peritonitis, with no Treatment, with Enterostomy and with Administration of a Solution of Sodium Chloride*

Number of Dogs		Average Length of Life
8	General peritonitis .....	4 1/8 days
8	General peritonitis; ileostomy.....	3 1/9 days
6	General peritonitis; ileostomy; treatment with 1 per cent solution of sodium chloride.....	10 1/3 days

anesthesia, preferably through an incision in the upper left rectus muscle, using the first loop of small intestine that presents itself. When the distended bowel is drawn into the wound, it should be emptied of its local contents with a trocar attached to a suction pump. If the flow is too rapid and soiling is likely to occur, intestinal clamps may be used to isolate a section of the intestine. The operation should be done by the Witzel method and the catheter drainage tube should be passed through the omentum before closing the wound, as suggested by C. H. Mayo.

While it is doubtful if the toxemia and death in general peritonitis is due chiefly to intestinal obstruction, ileus should always be considered a complication and given due consideration in the treatment.

The importance of dehydration and hypochloremia should be recognized in the treatment of patients with general peritonitis. The experi-

mental evidence presented indicates that life may be much prolonged by administering large quantities of a solution of sodium chloride.

### CONCLUSIONS

1. Sufficient evidence has not been presented to justify the belief that the cause of death in general peritonitis is intestinal obstruction alone.

2. Enterostomy is of no value in the treatment of dogs in which fulminating general peritonitis has been produced. It is probably of doubtful value in such cases in man.

Chart 3.—The subcutaneous administration of a solution of sodium chloride prevents the typical changes in blood chemistry observed in experimental general peritonitis and prolongs the life of animals.

3. In selected cases of peritonitis of the lower part of the abdomen, enterostomy is life saving.

4. In doubtful cases of peritonitis, enterostomy should be used. If proper technic is used, it can do no harm and may do much good.

5. No treatment for peritonitis should be given to the exclusion of large quantities of a saline solution to relieve the dehydration and hypochloremia.

# POSTOPERATIVE PNEUMONIA \*

MORRIS K. SMITH, M.D.

AND

PAUL C. MORTON, M.D.

NEW YORK

Postoperative pneumonia, despite the study it has received, remains a dreaded complication of surgical therapy. In an assembled table of figures from clinics here and abroad, Cutler and Hunt<sup>1</sup> found that in operations on 41,368 patients there was an incidence of pneumonia of 1.12 per cent. 46 per cent of whom died—a mortality by operation of about 0.5 per cent. These figures require explanation, however. The apparently low general mortality of 0.5 per cent is greatly increased in certain operations, notably those on the stomach, as will be discussed later. On the other hand, the high death-rate in those cases in which pneumonia develops is due to a considerable extent to the association of other grave conditions. Among patients who were well and came in for an operation of choice and then developed pneumonia Whipple<sup>2</sup> found only nine deaths in sixty-one cases, a mortality of 15 per cent.

The present study is based on 128 case reports taken from the files of the general surgical services at St. Luke's Hospital for the ten year period from July, 1918, to July, 1928. However, as the records were less accurate for the earlier part of this time, the five year period from January, 1923, to January, 1928, has been used for the estimation of morbidity. For these five years, the autopsy protocols as well as indexes from the record room have been searched, and a considerable number of cases thereby added. Records of pneumonia occurring after operation on the lungs and pleura as well as a few cases of pneumonia of the terminal type which did not have any connection with the operative procedure have been omitted. During this period 10,835 operations were performed in the general surgical services, with the exception of those done in private cases; pneumonia occurred in eighty-seven cases, an incidence of 0.8 per cent (table 1). Among the eighty-seven there were fifty-one deaths, a mortality of 59 per cent and a mortality by case of 0.5 per cent; the latter figure coincides with that in the table of Cutler and Hunt. If the cases in which the pneumonia seemed only a

secondary cause of death are excluded, there were twenty-two fatalities among eighty-two cases in the ten year period—a mortality of 27 per cent.

The cause of postoperative pneumonia remains much discussed, and as a knowledge of etiology is the key to prevention, this problem forms the crux of our inquiry. The principal theories of causation are: anesthetic, atelectatic, embolic and inhalation. They overlap to an extent.

#### REVIEW OF CAUSES OF PNEUMONIA IN GENERAL

Some causal and predisposing factors in lobar pneumonia mentioned by Cecil<sup>3</sup> follow: . . . it is probable that a considerable proportion of the pneumonia caused by pneumococcus type III and type IV is traceable to organisms which the patient has been carrying for some time in his mouth. . . . Carriers of virulent pneumococci probably play an important part in the dissemination of the disease. . . . Pneumonia . . . is most common among the poor and badly nourished. . . . Fatigue is one of the most important predisposing factors, especially when chilling of the body takes place after profuse perspiration. . . . exposure to cold of any kind is undoubtedly an important factor." January, February and March show the greatest incidence of the disease in New York City.

Bronchopneumonia is principally a secondary disease. Important contributory factors to its development under special conditions are inhalation of irritating gases and aspiration of food or other foreign particles (Dochez<sup>4</sup>).

#### FACTORS OF POSTOPERATIVE PNEUMONIA WHICH HAVE A BEARING ON ITS ETIOLOGY

In the majority of cases, pneumonia begins within the first two days following the operation, as shown in the accompanying chart. In many of these cases a tenacious mucus is present in the air passages, and the

3. Cecil, R. L.: Lobar Pneumonia, in Text-Book of Medicine, edited by R. L. Cecil, Philadelphia, W. B. Saunders Company, 1927, p. 15.

4. Dochez, A. R.: Broncho-Pneumonia, in Text-Book of Medicine, edited by R. L. Cecil, Philadelphia, W. B. Saunders Company, 1927, p. 43.

patient finds difficulty in expectorating, due in part at least to the pain of coughing. There is, however, a definite group in whom the onset is late, from the fifth to the twelfth day, for the most part.

Postoperative pneumonia is lobular in the majority of cases. In only three of the thirty-six autopsies in this series was lobar pneumonia reported.

Gas and ether given by the closed method was the anesthetic employed in a large proportion of our cases, although there are instances of pneumonia occurring after gas and oxygen, ethylene and local

Incidence of postoperative pneumonia.

anesthesia. The observations of the incidence of pneumonia after local anesthesia as opposed to that after general anesthesia are particularly interesting in a discussion of etiology. In a series of laparotomies von Mikulicz<sup>5</sup> found a slightly higher incidence and mortality in the patients operated on under local infiltration. In a series of cases from Hochenegg's clinic, Mandl<sup>6</sup> did not find a striking difference; local

5. Von Mikulicz, J.: Die Methoden der Schmerzbetäubung und ihre gegenseitige Abgrenzung, *Verhandl. d. deutsch. Gesellsch. f. Chir.* 30:575, 1901.

6. Mandl, F.: Zur Statistik der postoperativen Lungenkomplikationen und über erfolgreiche Bestrebungen zu deren Prophylaxe, *Deutsche Ztschr. f. Chir.* 165:67, 1921.

anesthesia was favored slightly. It is interesting to read that the problem of pneumonia concerned surgeons in the preanesthetic era. In an early number of *Guy's Hospital Reports*, Chevers<sup>7</sup> described forty-seven instances of pneumonia among 153 autopsies on patients dying after injuries and operations; according to the writer, this occurred in a hospital in which the worst forms of infection were not particularly prevalent.

All writers point out the high incidence of postoperative pneumonia after laparotomies, particularly those in the upper part of the abdomen. Cutler and Hunt,<sup>1</sup> in an assembled table, found a morbidity of 4.48 per cent. In our own series the morbidity after laparotomies, including those for inguinal and ventral hernia, is 1.2 per cent as opposed to 0.3 per cent after other operations, a proportion of 4:1. If upper abdominal operations alone are considered, the incidence rises to 2.7 per cent. Of the twenty-two cases in this series in which the pneumonia is considered the main factor in the fatal issue, laparotomies were performed in seventeen, in ten of which the operations were performed for peptic ulcer or gastric carcinoma. Elwyn<sup>8</sup> emphasized the susceptibility to pneumonia when operations have been done on the stomach, reporting an incidence of 14 per cent, which is twice as great as the incidence when operations have been performed on the intestinal tract or the gallbladder.

Operations in the presence of infections of the upper air passages carry a much increased liability to pulmonary complications. Whipple<sup>9</sup> found a morbidity of 15 per cent in patients giving a history of recent or concurrent cold, as opposed to the general incidence of 2 per cent or less. In this series, seventeen patients had a disturbance of the respiratory tract, usually a cold, at the time of operation. The pneumonia began in the first two days in a higher percentage of these patients than in those of the whole series. Of the twenty-two deaths attributed primarily to pneumonia, seven occurred in this group.

We have no statistics to prove that a badly taken anesthetic means a greater liability to pneumonia, but nevertheless we are apprehensive under such circumstances, and many share this feeling. A patient of the senior author was operated on for an umbilical hernia. He was a stout man with a short neck and did not take a full breath after the commencement of the anesthesia. He remained choked up, and died on the third day. The clinical diagnosis was bilateral pneumonia.

9. Whipple, A. O.: More Recent Studies upon the Etiology of Postoperative Pneumonitis, *New York State J. Med.* 26:967, 1926.

In studying the fatalities among our cases of postoperative pneumonia, we have been impressed by the number in which sepsis and debility have played an important part in the cause of death. Of sixty-eight deaths, twenty-two seemed to be due primarily to pneumonia; twenty-two of the patients were septic and fifteen were debilitated by age, malignant disease and toxemia. There remain nine whose cases it seemed impossible to classify. If the whole series is grouped by decades, the lowest mortality figure is found in the 21 to 30 age group. It rises steadily in both directions.

Whipple<sup>2</sup> showed that the pneumococcus group IV is the common organism found in the sputum in postoperative pneumonia. The results of examinations recorded in our series are in agreement with this.

Although occurrence by months does not give an even curve, there is a seasonal variation over the period studied. March leads all the other months by a wide margin in incidence, and the four month period, January, February, March and April, is well in the lead over the other two succeeding four month periods. July shows the lowest monthly incidence.

#### EXPERIMENTAL OBSERVATIONS OF INTEREST

Coryllos and Birnbaum<sup>10</sup> concluded from their investigations on atelectasis that in the absence of compression of the lung by effusion, pneumothorax, etc., the condition is always due to the complete occlusion of a large or small bronchus. They said that infectious complications in the atelectatic area seem inevitable when the occlusion remains complete for more than seventy-two hours.

Cutler and Schleuter<sup>11</sup> produced extensive pneumonia in the lung by the insertion of infected pieces of meat and tonsil into the jugular vein.

Lemon<sup>12</sup> showed that solutions dripped into the pharynx of anesthetized dogs are aspirated into the lungs. The danger is least when the subject is in the Trendelenburg position and greatest when the head is higher than the body.

Myerson<sup>13</sup> performed bronchoscopy in a series of 100 patients undergoing tonsillectomy under general anesthesia. In seventy-nine of them he found blood and pharyngeal secretions in the tracheobronchial tract.

## COMMENT

In the discussion of the etiology of postoperative pneumonia, it seems to us that the question of the route of infection, important as it is, sometimes receives undue emphasis to the neglect of causes recognized as important for pneumonia in general. We have seen that preceding respiratory infection, debility and sepsis are frequent in postoperative pneumonia as in other types of this disease. We believe that serious chilling is an important factor. Who of us, after indulging in exercise to the extent of being drenched with perspiration and then falling asleep, half covered, in a draft, would not consider it fortunate if he escaped pneumonia? Yet the experience of the patient on whom an operation has been performed is often comparable. During the course of an operation, he is subject to chilling and shock. He perspires freely. Recovering in a ward, he often tosses his bed clothes partly away and exposes himself to the drafts inevitable in rooms with large windows and doors. The increase in incidence of pneumonia in winter and in the early spring shows, to our minds, both the influence of cold and changing weather and that contagion is transmitted by carriers of virulent organisms. In a study from Hochenegg's clinic in Vienna, Mandl<sup>14</sup> reported

14. Mandl, F.: Zur Statistik der postoperativen Lungenkomplikationen und über erfolgreiche Bestrebungen zu deren Prophylaxe, Wien. klin. Wchnschr. 34: 214, 1921.

that in the winter of 1919-1920 when, on account of the shortage of coal, operating rooms and wards were insufficiently heated, there was a great increase in postoperative pneumonia.

When one examines the local causes of postoperative pneumonia, the anesthetic itself as the direct inciter is mentioned merely because the term ether pneumonia has been so widely used. We know of no evidence to the effect that it acts other than indirectly as an irritant, causing increased secretion.

Since massive collapse has been recognized, it has been suggested that smaller areas of collapse are in reality the condition in many so-called postoperative cases of pneumonia (Lee, Tucker and Clerf,<sup>15</sup> Elwyn<sup>16</sup> and Featherstone<sup>17</sup>). Elwyn<sup>16</sup> was led to this belief by finding collapse at autopsy in four cases diagnosed clinically as pneumonia. Furthermore, he stated that on the day after operation in patients on whom a laparotomy had been performed he repeatedly found dulness and diminished breath sounds over the whole or part of a lobe, which to his mind signified atelectasis. If infection by way of the bronchial tubes is added, true pneumonia may develop.

Coryllos and Birnbaum<sup>10</sup> pointed out that while obstruction of the bronchus is the determining cause of atelectasis, contributing causes are embarrassment of respiratory movement, increased bronchial secretions and decrease or abolition of the cough reflex. These conditions are found in laparotomized patients. If the plug of mucus is not cleared, infection will ensue.

Whipple<sup>9</sup> reported that in only two of his cases coming to autopsy had the condition of partial lung collapse been found. In none of our cases clinically called pneumonia was massive collapse diagnosed at autopsy. It would, of course, be more to the point if the lungs of the patients recovering promptly could be examined. It seems reasonable to us to believe, however, that areas of atelectasis are the starting point of pneumonia in some, perhaps in many, cases.

Cutler<sup>1</sup> came to the conclusion that in the majority of cases postoperative complications are due to embolism from the operative field. He believed the causes of infarction to be: (1) trauma, (2) the mobility of the part and (3) sepsis. It has already been pointed out that operations on the upper part of the abdomen, where the mobility of the field is great, are particularly liable to be followed by postoperative pneumonia, and that sepsis is frequently a part of the condition when this

complication appears. A further argument for Cutler's point of view is the common occurrence of this complication after a local anesthetic and after a general anesthetic, even when given by the most expert anesthetizer.

One of the strongest arguments against the embolic theory as the common cause of postoperative pneumonia is its prompt onset in the large percentage of cases. While we know that pulmonary emboli recognizable as such occur early, experience shows that they are most frequent during the second week (Wilson).<sup>18</sup> In our postoperative cases in which autopsy is performed, infarcts are infrequently reported.

That embolism is, however, an important cause of postoperative pneumonia we think is clear. The smaller group of late origin occurs at the same period as do massive emboli. By this time, such factors as exposure incident to the operation and recovery, inability to cough and increased bronchial secretions are no longer effective.

We believe that infection by way of the air passages is the most logical explanation for the larger group of early postoperative types of pneumonia, whether or not the pneumonia is engrafted on areas of atelectasis. The work of Lemon,<sup>12</sup> Myerson<sup>13</sup> and Blake and Cecil,<sup>3</sup> as well as that of others, demonstrates that the bronchial route is a possibility. The danger of operation in the presence of an infection of the upper respiratory tract and the fact that the organism most commonly recovered is pneumococcus group IV, an organism often present in healthy throats, are strong evidence that this tract is the route of infection.

Terry<sup>19</sup> found that of operations on the lower part of the abdomen, those done in the Trendelenberg position are less liable to be followed by postoperative pulmonary complications. This, in connection with Lemon's work on dogs, suggests the importance of aspiration. Terry was furthermore able to reduce the incidence of pneumonia by painting the gums with a bacteriostatic solution preoperatively.

To our minds, the etiologic factors are somewhat as follows: The general resistance, often low because of the poor condition, is depressed by chilling and shock. Bronchial secretions are likely to have been increased because of irritation by the anesthetic and after operation by congestion from immobility and lack of free respiration. After laparotomies, particularly, cough is painful and ineffectual. Areas of atelectasis may develop. We have, then, both general and local conditions favorable to lodgment of whatever infectious organisms may have

been present or aspirated from above. In septic cases, undoubtedly the source of infection is often from the primary focus via the blood stream, but it would seem that otherwise the route through the air passages explains all the facts most satisfactorily in the large group of cases of early postoperative pneumonia.

#### DIAGNOSIS

While it is a temptation to attribute an unexplained postoperative rise in temperature to pneumonia, it is undoubtedly often overlooked in the presence of other grave complications. In thirty-six autopsies in this series which revealed pneumonia, the condition was apparently unsuspected in twelve. There were also four cases in which the clinical diagnosis of pneumonia was made but not confirmed at autopsy. The diagnosis in two of these cases was edema and congestion, in one infarction and in one metastatic tumor with pleurisy.

#### PREVENTION AND TREATMENT

We would emphasize the following points: Operation should not be performed in the presence of infection of the upper respiratory tract except in an emergency. In such cases, we believe local anesthesia is safer. It is wise to postpone operations of choice in seasons when pneumonia is particularly prevalent. A skilfully given anesthetic and skilled postoperative nursing care are important in minimizing aspiration of throat secretions and vomitus. The greatest care should be exercised to prevent chilling the patient during operation, in the trip from the operating room to the ward and during recovery. Avoidance of shock and unnecessary trauma in the operative procedure is important for the prevention of pneumonia as well as for other reasons. After the operation, the patient should be turned frequently to prevent pulmonary stasis. If the condition suggests the onset of atelectasis, an effort can be made by posture and slapping, as described by Gibson,<sup>20</sup> to dislodge the plug of secretion.

# THE AVERAGE TREATMENT OF CANCER

## II. REPORT OF THE STUDY OF THE DEATHS FROM CANCER IN DETROIT DURING SIX MONTHS FROM MAY 15 TO NOVEMBER 15, 1927 \*

HARRY C. SALTZSTEIN, M.D.

AND

DAVID J. SANDWEISS, M.D.

DETROIT

All deaths from cancer occurring in Detroit during the six months from May 15 to Nov. 15, 1927 were studied. Data were also obtained on all operations for cancer of the breast and alimentary canal at all Detroit hospitals during the same period. (Many of these patients did not die.) In a few instances, especially in persons with cancer of the breast and cervix, the study included those dying during the next six months.

A blank form was devised which contained on the first page the information on the death certificate and data about admissions to hospitals, etc.; on the two inside pages was listed a series of questions about cancer, grouped in eight different regions of the body and arranged for (a) precancerous symptoms, (b) symptoms of cancer and (c) signs on examination at the time the diagnosis was made. On the back of the blank was recorded information about the treatment and the course following treatment. At the end were a few questions relating to the possible control or prevention of this person's death. The following method was employed:

First, the physician who had signed the death certificate was telephoned, and such information about the patient as he had was secured; second, the data obtainable from hospital charts when the patient had been treated at any of the hospitals in the city (or elsewhere) were obtained, and third, further information was obtained from physicians who may have seen the patient before he or she entered the hospital. \* The spirit of cooperation shown by the entire medical profession and all of the hospitals was splendid, and all the information asked for was given. There was a daily contact with perhaps ten or fifteen physicians by telephone messages throughout the course of this study. Several physicians made house calls on the families of their former patients and aided us in other ways

---

\* Submitted for publication, Dec. 27, 1928.

\* While these data were being collected, an opportunity to make a survey of the facilities available for the treatment of cancer in twenty cities presented itself (Saltzstein, H. C.: *The Average Treatment of Cancer*, J. A. M. A. 91: 465 [Aug. 18] 1928). When inquiries about similar facts were made, the figures for the twenty cities agreed quite closely with those obtained here. This article is presented, therefore, as a detailed (although perhaps somewhat incomplete) picture of the diagnosis and treatment of cancer in one community, which, unless there is some special institute or there are more than the usual medical facilities available, will in all probability be duplicated quite generally in the typical American city

\* The data were collected through the Cancer Division of the Department of Health in association with the Wayne County Medical Society.

to obtain this information. During the six months there were 466 deaths certified as having been due to cancer. When the data were finally completed, we had information on all but 19 cases, leaving 447 cases for detailed study.

### RESULTS

The first point on which information was desired was as to how accurate the diagnosis of cancer was when the death certificate designated that the patient had died of this disease. After collecting all of the data on these cases, the examiners were of the opinion that in only 16 instances, 3.6 per cent, the final diagnosis should not have been cancer. These data are supplemented by 225 additional subsequent cases, in which 6 diagnoses were changed, so that in 672 deaths from cancer, 22 final diagnoses were changed, 3.3 per cent (table 1). Many of these 22 patients had been only briefly observed by a physician during the ter-

TABLE 1.—*Changes in the Death Certificate Diagnosis of Cancer in Six Hundred and Seventy-Two Consecutive Deaths (Twenty-Two Changes, 3.3 Per Cent)*

1 cancer of stomach	changed to ulcer of stomach
1 cancer of stomach	changed to cardiac condition
1 cancer of stomach	changed to peritonitis probably from appendix
1 cancer of stomach	changed to alcoholism
1 cancer of rectum	changed to cardiac condition
1 cancer of rectum	changed to pathologic condition with a diagnosis negative for cancer
1 cancer of uterus	changed to chronic endocervicitis with hypertrophy
1 cancer of uterus	changed to degenerate fibroid
1 cancer of mouth	changed to Vincent's angina
3 cancers of liver	changed to cirrhosis of liver
1 cancer of liver	changed to hemiplegia following fracture of bone
1 cancer of pancreas	changed to nephritis
1 cancer of ovary	changed to pathologic diagnosis—tuberculosis
1 cancer of omentum	changed to cardiac condition
In 225 additional cases, 6 diagnoses were changed:	
1 cancer of stomach	changed to cardiac death
1 cancer of stomach	changed to ulcer of stomach—postoperative death
1 cancer of stomach	changed to ulcer of duodenum—postoperative death
1 cancer of pancreas	changed to pancreatic cyst following trauma, with postoperative death
1 general cancer	changed to tuberculous peritonitis
1 general cancer	changed to cardiac death

iminal stage of the disease, and hospital data or other sources revealed more detailed information than had been obtained when the death certificate was signed. In these 22 cases the most frequent error was the confusion of abdominal cancer with a cardiac condition; 5 deaths in which the cause was designated as abdominal cancer were finally felt to be due to cardiovascular disease—chiefly cardiac failure. Three diagnoses of cancer of the liver were finally classified as due to cirrhosis, and in two diagnoses of pelvic cancer the hospital records showed tuberculosis in microscopic section. In two cases in which the condition was diagnosed as carcinoma of the uterus the diagnosis was changed to degenerated fibroid in one and in the other to chronic endocervicitis with hypertrophy of the cervix (a postoperative death). A far greater error lies in those cases in which death supposedly occurred because of heart trouble, "old age," cirrhosis, etc., but in which the real cause was cancer. We have no information concerning that error here. It has been held to be as large as 50 per cent in all middle-aged persons who die of obscure ailments.

This left 431 deaths in the original six months studied positively considered due to cancer. Of these there were 32 instances in which after all data were obtained, the location (organ involved) of the primary cancer was different from that which appeared on the death certificate. Table 2 indicates this with the changes which were made. The chief importance is in the group of cases of general abdominal cancer in which on closer investigation the source of the growth was thought to have been better determined.

Table 3 shows the total number of deaths from cancer during this six months period, divided according to organs involved as finally corrected. There were 466 death certificates; 16 diagnoses were changed, leaving 450 deaths from cancer.

TABLE 2.—*Four Hundred and Thirty-One Cases in Which the Diagnosis of Carcinoma as Marked on the Death Certificate Was Correct, but in Which the Site of Origin (Organ Involved) was Changed on Closer Analysis (Thirty-Two Changes, 7.4 Per Cent)*

10 carcinomas of stomach changed to	1 carcinoma of breast changed to
2 carcinomas of liver	1 carcinoma of kidney
4 carcinomas of rectum	
1 carcinoma of upper abdominal organs*	9 carcinomas of mouth changed to
1 carcinoma of uterus	1 carcinoma of stomach
1 carcinoma of breast	3 carcinomas of lips
1 general carcinoma*	5 general carcinomas*
1 carcinoma of rectum changed to	1 carcinoma of kidney changed to
1 carcinoma of stomach	1 carcinoma of stomach
4 carcinomas of uterus changed to	6 carcinomas, abdominal, changed to
1 carcinoma of stomach	1 carcinoma of stomach
2 carcinomas of ovary	1 carcinoma of rectum
1 carcinoma of kidney	1 carcinoma of uterus
	1 carcinoma of breast
	2 carcinomas of kidney

\* In these cases it was not thought that there was sufficient evidence to warrant a final diagnosis of cancer of the particular region of the body designated.

The data previously indicated were obtained in all of these cases. It was finally felt, however, that such cases as carcinoma of the esophagus, pancreas, liver, nasopharynx, sarcoma and many of the group named general did not offer much from the standpoint of possible control. Therefore, in further work these groups may be eliminated. They represent approximately 23 per cent of the total.

In this investigation, the points kept in mind were: first, the collection of clinical data about a large number of cases of cancer; second, the difficulties encountered in making an early diagnosis; third, the possibilities of popular education in combating the delay between the onset of symptoms and the first visit to the physician and fourth, the effectiveness of the treatment.

It was sometimes difficult to obtain complete data about the early history of the illness, but we probably obtained fairly complete data about the treatment. We feel that a study of this sort is more valuable as an index and a record of the treatment for cancer than anything else. Our records have frequently traced patients through several hospitals

and thus have often been more complete than those any one institution would have.

Since the early symptomatology and the treatment for cancer in the different regions of the body vary so tremendously, it was not thought of much interest to combine statistics for cancer of the esophagus, uterus, skin, etc. Accordingly, cancer in each region of the body will be considered separately.

#### BREAST

There were forty-three deaths from cancer of the breast during these six months. In one, the data were unobtainable, which left forty-two for study. During this time, ninety-five operations for cancer of the breast were recorded at all of the hospitals of the city. Thus, subject to errors in the method, there are twice as many people being operated on for cancer of the breast in a given period of time as die from the disease—ninety-five operations and forty-three deaths.<sup>1</sup>

Enough patients were operated on to enable us to contrast the various hospitals as to grouping, methods, etc. The largest number were oper-

1. The chief errors in the method are: Some of the patients operated on in Detroit lived outside of the city and hence, probably died elsewhere. From hospital records, about 10 per cent of the patients operated on in Detroit came from out of town. The other error is represented by patients operated on elsewhere and subsequently dying in Detroit. This was exactly 10 per cent, so that these errors counterbalance each other.

ated on in hospital 1—thirty-nine cases, or 41 per cent of the total number of operations in the city during the six months. The smallest number were operated on at hospital 4, the Receiving Hospital, a free city institution. The number of amputations of the breast for cancer does not depend on the size of the hospital but on the number of private surgical beds and the private surgical practice of the individual surgeons in the hospital.<sup>2</sup>

In hospital 1 a considerable amount of concentration of patients was apparent, twenty-eight of the thirty-nine having been operated on by three surgeons or their associates. Similarly, at hospital 3 eleven of the total thirteen operations were performed by two surgeons. At hospital 2, thirteen operations were performed by ten surgeons, no one man doing more than two operations. At this hospital three radical operations were listed, and ten were designated in the records as simple mastectomy or semiradical resections. There is a body of medical opinion which holds that irradiation can better cope with glandular metastases than can radical operations, and according to this opinion, when the axilla is heavily invaded, it is better to remove the breast and the glands that are easily excised and then use irradiation than to do a primary radical resection. In the other hospitals few cases were listed in which anything but radical amputations had been done (table 4).

In the following computations, to the forty-two cases in which death occurred during the six months are added thirty-three additional ones in which death occurred during the second six months, making a total of seventy-five consecutive cases of cancer of the breast in which data were complete enough for study. Seventeen of these seventy-five patients (22.6 per cent) did not receive treatment (operation) during the entire course of the illness. Most of them had refused operation, or when they came to a physician the breast was an extensive ulcerating hopeless mass. The average total duration of the illness in these untreated patients was 32.1 months.<sup>3</sup> Fifty-eight patients were operated on, and their average total duration of illness was 41.6 months (9.5 per cent months longer than in the untreated patients).<sup>4</sup> The average duration of symptoms

---

2. Saltzstein, H. C.: *The Average Treatment of Cancer*, J. A. M. A. **91**:465 (Aug. 18) 1928.

3. Daland found the average duration of 100 untreated patients with cancer of the breast to be 40.5 months. Other published figures vary from 27 months to 48 months (Daland, E. M.: *Untreated Cancer of the Breast*, Surg. Gynec. Obst. **44**:264, 1927).

4. These and all similar computations in this study do not take into account patients who have not died or who have died of intercurrent diseases. All results must be interpreted with this error in mind. It is felt, however, that considering the small number of patients who survived more than one or two years after treatment, this error cannot have been very large. This applies especially to cases of cancer of the cervix. It must also be borne in mind that the number of patients who were treated is too small on which to base any conclusions except as they indicate general trends.

before diagnosis in the patients operated on was 9.4 months and in the untreated patients, 21.3 months. As nearly as our reports indicated, most of the delay must be attributed to the patient, because we have no records of patients with cancer of the breast who have been medically observed for any length of time, and only a few (four or five) who were advised that the lump in the breast should be let alone.<sup>5</sup>

Concerning the efficacy of the operation as it was performed and the stage in which these fifty-eight patients came for treatment, the average postoperative life was 29.6 months (including four postoperative deaths). Though several patients died after being free from the disease for several years (five had freedom from recurrence for more than seven and one-half years), nevertheless in forty-eight of these fifty-eight cases (82.7 per cent) the disease recurred within two years of the operation. Four died postoperatively; sixteen were not free from recurrences. The average duration of postoperative freedom from recurrence in the remaining forty-two cases was 30.7 months<sup>4</sup> (table 8).

#### STOMACH

The entire number of deaths in patients with cancer of the stomach, esophagus, pancreas, gallbladder, liver and upper part of the abdomen included 171 of the total 450 deaths, approximately 38 per cent. As noted in table 3, 14 cases were classified as cancer of the esophagus, 10 of the pancreas, 8 of the gallbladder, 9 of the liver and 8 of the upper part of the abdomen. Probably several of the cases finally classified as carcinoma of the liver and upper part of the abdomen originated in the stomach, but we had no way of being sure of this. That left 122 cases of carcinoma of the stomach. In nine of these cases data were insufficient, so that 113 cases of cancer of the stomach remained for detailed study.

Eighty-six of these 113 patients did not receive treatment (operation). They lived on an average of 13.9 months from the onset of the symptoms until death. Twenty had palliative operations (gastroenterostomy, exploratory laparotomy, gastrostomy). The average total duration of the illness was less than in those who did not receive treatment—13.3 months. Seven had radical resections. They lived just six and one-half months longer than the untreated patients—the average total duration of their illness being 20.4 months.<sup>4</sup>

In 105 of the 113 cases information was obtained in regard to the duration of the symptoms of cancer before the diagnosis. The duration ranges from one month to thirty-six months, the average duration of

---

5. This impression was also definitely gained in the survey in twenty cities; surgeons uniformly reported that physicians did not usually delay treatment in persons with cancer of the breast, but that 75 or 80 per cent of their patients already had axillary involvement when they were operated on. It can only mean that further lay publicity is necessary in cancer of the breast.

symptoms from the onset to the time of diagnosis of cancer being 11.4 months (table 8).

A large number of these cases show a long period of medical observation before the diagnosis was made. In twenty-six of the 113 cases, information was obtained in regard to medical observation before gastric cancer was diagnosed. These cases had been medically observed for periods ranging from two months to two years before the diagnosis was made, the average medical observation being 8.5 months. This contrasts with the data we obtained in cases of cancer of the breast in which, using similar inquiries, we learned of only four or five cases in 75 studied that had been medically observed for longer than one month before the diagnosis was made.

Few of the total number of patients who have cancer of the stomach are operated on. There is a profound pessimism among physicians regarding the utter impossibility of diagnosing cancer of the stomach soon enough to effect any radical treatment. The early histories in these cases were studied with the possibility of earlier diagnosis in view.

In ninety-six cases in which the information was obtained, eighteen (18.7 per cent) gave a history of preceding indigestion and in the remaining seventy-eight cases (81.3 per cent), the onset started (as near as we know) after a period of perfect health. However, of these seventy-eight cases in which the onset began after previous perfect health, in all but seven (8.9 per cent) the onset occurred with indigestion, of either mild or more severe type. In the latter small group (8.9 per cent), the onset of cancer was marked chiefly by anemia, weakness or pain in the chest, symptoms apparently impossible of diagnosis. It is felt that in a large proportion of those cases in which the condition started after previous indigestion the diagnosis could have been made soon enough for radical treatment, and that in many of those starting after previous good health the diagnosis could have been made sooner. The deaths from cancer of the stomach make up such a large group of the total deaths from cancer (27.2 per cent of the total) that effort here should not be worthless.

Our data show that the clinical picture of mild indigestion, gas and discomfort after meals as indicating possible carcinoma of the stomach is not appreciated by the medical profession at large in the way that the significance of a lump in the breast is appreciated.

Of the 113 cases studied, table 5 shows the number of patients operated on, the type of operation and the length of life postoperatively.

Thus, seven of the 113 patients (6 per cent) had had radical resections. The three who survived this operation lived seventeen months, twenty-five months and fifty-two months, respectively, before they died of recurrence. It is to be noted also that the average operative mortality

from gastro-enterostomy and exploratory laparotomy in cancer is high. This has been noted in previous studies.<sup>6</sup> For comparison, the total number of operations for cancer of the stomach performed in all the hospitals in Detroit during the period of study was collected. The material is slightly different, for some of the patients represented in table 5 were operated on before May 15 and some of those in table 6 died after May 15 or outside of Detroit.

The relatively small number of patients with cancer of the stomach who are submitted to radical operation and removal of the growth and the attendant high mortality are perhaps not sufficiently appreciated. In 1925 and 1926, a total of twenty-eight gastrectomies for cancer of the stomach were performed in Detroit; there were thirteen deaths, an operative mortality of 46.3 per cent.<sup>6</sup> The survey previously mentioned<sup>2</sup>

TABLE 5.—*Total Operations Performed on One Hundred and Thirteen Patients with Cancer of the Stomach Who Died in Detroit from May 15 to Nov. 15, 1927*

showed that during 1927, in seventy-five hospitals in nineteen cities sixty-seven gastrectomies for cancer were performed. Twenty-seven of these patients died following operation, a mortality of 40.3 per cent. In both of these estimates, the number of gastrectomies for cancer is about 6 per cent of the total mortality from cancer of the stomach.<sup>7</sup> If the 40 per cent operative mortality is subtracted, not more than 4 per cent of the total number of persons with cancer of the stomach have the

6. Saltzstein, H. C.: Further Experiences with Publicity in Cancer, J. A. M. A. 89:1541 (Oct. 29) 1927.

7. In Detroit, during 1925 and 1926, there were 717 deaths from cancer of the stomach; in 28 of the cases (5.5 per cent) gastrectomies were performed. In nineteen cities, the estimation being based on Detroit's population and death rate from cancer of the stomach (excluding cancer of the esophagus, pancreas, etc.), there were 1,072 deaths from cancer of the stomach and 67 gastrectomies, 6.1 per cent.

chance of cure which operative recovery from gastrectomy for cancer represents.

#### RECTUM AND COLON

There were nineteen deaths from cancer of the rectum during the six months. The hospitals recorded five radical excisions with three operative deaths during this period. There were twelve deaths from cancer of the colon, exclusive of cancer of the sigmoid; during this time, four radical resections and three operative deaths were recorded. Fifteen deaths occurred from cancer of the sigmoid, with eight operations and four recoveries—a higher percentage than the others. Thus, during the time when there were forty-six deaths from cancer of the colon and rectum, there were eighteen radical resections with eight operative recoveries.

Table 7 shows the number of deaths from carcinoma of the rectum and colon and the number of radical operations, with the results

‡ Operative recovery.

obtained. Although proportionally many more radical operations were attempted in cases of cancer of the colon and rectum than in those of cancer of the stomach, nevertheless the cases are still too few and too scattered for the best results to be obtained. There were three resections of the rectum at hospital 1 with three deaths, and two resections of the sigmoid at hospital 3 with one death. Otherwise, the figures are all ones.

Several patients came to operation with signs of peritonitis or obstruction, having been in fair health before the operation. The impression gained was that mild flatulence, constipation and lower abdominal colics, as symptoms of cancer of the large bowel are not generally appreciated. One patient was in the hospital for observation, discharged, then readmitted the next week and operated on, extensive peritoneal metastases being found. In four cases, the cancer had perforated the wall of the intestine, causing peritonitis at the time of operation. One of these pointed in the pelvis and was drained vaginally, the cancer being found only post mortem.

The clinical data in these cases of carcinoma of the colon and rectum are interesting from the standpoint of medical observation before diagnosis and the type of operation done; however, this will be analyzed later after reports of more cases have been collected.

#### LIP AND LARYNX

Only six deaths from cancer of the lip occurred during the six months period. One patient had received escharotic treatment, with freedom from recurrence for three months. Another lived two years after escharotic treatment. Three had had local excision with or without external irradiation. There was from one to two years postoperative freedom from recurrence. One had freedom from recurrence for four years following diathermy resection.

In two of the foregoing cases, notes by the pathologist indicated that the excision was not wide enough. Nothing further had been done in either instance. Patients with cancer of the lip lived longer with recurrence than did any other group, and some of them had repeated operations.

Seven cases of cancer of the larynx were reported. Operation was not advised in any of these cases. The condition in all was considered hopeless at the time of diagnosis.

#### CERVIX

It is more difficult to obtain data covering the average treatment for cancer of the cervix because the irradiation treatment varies considerably, and hospital reports do not record the entire treatment as they do for one operation for cancer of the breast, for example.

To the reports of the sixty-four patients who died during the six months, thirty-six are added in which the patient died during the second six months, making a total of 100 consecutive cases in which data were complete enough for analysis. Twenty of these 100 patients died without having had any treatment which might have been curative (operation or irradiation). The average duration of life of these untreated patients was 17.5 months. In sixteen in whom abdominal or vaginal hysterectomy was performed and who died subsequently, the average total duration of illness was 24.8 months. In fifty-five patients who had received irradiation treatment, the average duration of the entire illness was 25.2 months. Thus, in this study of deaths, the patients treated lived six or seven months longer than those untreated.<sup>4</sup> Of the remaining nine patients, six had cauterization or amputation and no other treatment and three had abdominal exploration only; in three others, data about treatment were not obtained.

Regarding the effectiveness of the treatment, the average duration of life after treatment (irradiation or radical operation) was 14.2 months:

59.1 per cent died within one year, and 85.9 per cent died within two years.

A more accurate measure is how long after treatment the patient was free from recurrence, for if the disease recurs immediately and the suffering continues, nothing much has been accomplished by the treatment. Of the seventy-one patients who had either received irradiation or in whom a hysterectomy had been performed, thirty-one, or 43 per cent, either died following operation (one died shortly after irradiation) or had no freedom from symptoms following treatment. Eight, or 11.1 per cent, had doubtful freedom. In the remaining thirty-two (45 per cent) who were relieved following treatment, the average freedom

\* From analysis of all deaths in Detroit during six months to one year. Subject to the error of not including persons who have not died.

before suffering began was twelve months. In 84.5 per cent the cancer recurred within one year and in 94.5 per cent, in two years.<sup>4</sup>

Just why there is such a poor showing as regards the results of treatment for carcinoma of the cervix is not certain. Probably most of the reason is that the patients come so late for treatment. The average duration of symptoms before treatment was 10.2 months (10.9 months in the patients operated on and 9.3 months in the patients given irradiation).<sup>8</sup>

8. Purposely, further comparisons between the patients operated on and those given irradiation were not attempted since the numbers are not large, and the factors are probably too variable.

From his statistical study of the cases at Johns Hopkins Hospital, Martzloff concluded that for epidermoid cancers of the cervix "a duration of symptoms exceeding eight months is sufficient to put the patient beyond the scope of an operative cure;"<sup>9</sup> this probably holds true for irradiation therapy except in a small percentage of cases—at least with the quantity of radium usually available. Obviously, if the average duration of symptoms before diagnosis is nine or ten months and the case is hopeless if the duration of symptoms is beyond eight months, not many cures can be expected. Yet it is authoritatively stated that 30 per cent of patients with carcinomas of the cervix can be cured. Symposiums and discussions about the treatment for cancer of the cervix are apt to center about radium versus surgery in early so-called operable cases. It is not always apparent how small a percentage of the total cases this group represents.

The problem here concerns both the medical profession and the laity. We did not obtain data accurate enough for statistical analysis relating to medical observation of cancer of the cervix before the diagnosis was established, but the delay in medical observation is much greater and more frequent than is the delay in the recognition of a lump in the breast.

Lay education is difficult, for newspapers and the mixed audiences before whom addresses are given will not tolerate much discussion about "spotting," "discharge," etc., however gracefully the facts are put. Perhaps systematic brief addresses before all of the Women's Clubs or extensive circularization would accomplish more.<sup>10</sup>

#### SUMMARY

1. In a study of deaths from cancer occurring during six months, it was felt that 3.6 per cent of the patients certified as having died of cancer had died of some other disease.

2. In another 7.4 per cent, the site of the primary organ involved was changed.

3. Twice as many persons were operated on for cancer of the breast as died of the disease.

4. The concentration of cases of cancer of the breast for operation as well as the type of operation varied in the different hospitals.

5. Seventeen of seventy-five patients who died of cancer of the breast (22.6 per cent) were not operated on.

---

9. Martzloff, Karl H.: Cancer of the Cervix Uteri, Surg. Gynec. Obst. 47: 183 (Aug.) 1928.

10. Since this was written, it has been learned that the American Society for Control of Cancer is now engaged in extensive distribution through women's clubs, the Y. W. C. A., the Metropolitan Life Insurance Company and other organizations of circulars containing pertinent facts about cancer of special interest to women.

6. The average duration of symptoms of cancer of the breast before operation was 9.4 months.

7. There was no marked delay in medical observation in cases of cancer of the breast.

8. In fifty-eight operations in patients with cancer of the breast, the average postoperative life of those who died was 29.5 months. Five lived more than eight years after operation, but 82.7 per cent had recurrence within two years.

9. The average total duration of illness of eighty-six untreated patients with cancer of the stomach was 13.9 months. The total duration of illness of twenty patients who had palliative operations (gastro-enterostomy and exploratory laparotomy—gastrostomy) was 13.3 months. The total duration of illness of seven who had radical resection (dying subsequently) was 20.4 months.

10. In 105 patients with cancer of the stomach, the average duration of symptoms before diagnosis was 11.4 months.

11. In twenty-six of these cases in which the information was obtained, there was medical observation on an average of 8.5 months before diagnosis.

12. In 18 per cent of the cases of cancer of the stomach the onset occurred after previous indigestion. The remainder started as suddenly appearing indigestion in a middle aged person otherwise in good health.

13. The clinical picture of mild indigestion, gas, etc., as indicating possible carcinoma of the stomach, is not appreciated by the medical profession at large.

14. In few (about 6 per cent) cases of carcinoma of the stomach is radical operation performed. The operative mortality is high.

15. In cases of cancer of the colon and rectum the number of operations is high compared to the total number of growths. The cases are quite scattered and the operative mortality, especially of rectal cancers, is high.

16. Twenty of 100 patients with carcinomas of the cervix did not receive irradiation or radical surgical treatment.

17. The average duration of symptoms before diagnosis was 10.2 months.

18. Of seventy-one patients with cancer of the cervix who died, the average length of life after operation or irradiation was approximately fourteen months. Forty-three per cent of these were not free from symptoms following treatment, and an additional 11 per cent had doubtful freedom. In two years 85.9 per cent had died, and in 94.5 per cent the growth had recurred.

## CONCLUSIONS

This study has left the following impressions:

1. When evaluating any treatment for cancer, it is important to consider the average duration of life of the untreated patient.
2. In this series of deaths from the disease in Detroit (which probably represents an average situation), there does not seem to have been a great amount of benefit from treatment. The reasons are various: chiefly, most patients come for treatment too late, when the growth is already fixed and hopeless, and cases are too scattered to allow for the proper experience in their handling.
3. About 20 per cent of the persons who died from cancer of the breast had not been operated on. Twenty per cent of those who died of cancer of the cervix had not been operated on or received irradiation; 95 per cent of those who died from cancer of the stomach had not had a radical resection; that is, these persons had run the entire course of the disease without having had any treatment which might have been curative. If this is an indication of the general situation, it is too much to expect that efforts at publicity in the control of cancer will show great statistical proof of improvement, but it must be an indication of the need for further efforts of a consistent nature over a long period. In the matter of popular education for the control of cancer, the surface only had been scratched.
4. The clinical picture of mild abdominal indigestion in persons past middle life as due to possible cancer of the stomach or bowel is not recognized. Few cancers of the alimentary tract are radically resected, and the postoperative mortality is high.
5. The average results of the treatment for cancers of the cervix are not good.
6. Deaths due to cancers of the lip and skin constitute a relatively small proportion of the total deaths, and, accordingly, these cancers should not be considered a major problem in the control of cancer.
7. Chiefly because of the relatively few patients with cancer treated by any one physician and the inherent difficulties in a follow-up service, it is felt that end-results in general are not so well known as they should be. A central follow-up bureau embracing all institutions and persons in the city who treat cancer would register each year about 200 patients with cancer of the breast who had been treated, 100 with cancer of the cervix, and forty or fifty with carcinoma of the alimentary canal who may have had radical treatment. This is thought feasible.

# VASODEPRESSOR SUBSTANCES IN THE LIVER

AFTER OBSTRUCTION OF THE COMMON DUCT \*

I. S. RAVDIN, M.D.

PHILADELPHIA

For several years, it has been known that extracts from the liver have a depressor action when injected intravenously. Vincent and Sheen<sup>1</sup> showed this in 1903. They also demonstrated that the presence of choline in the extracts was insufficient to explain the effects obtained after intravenous injection, since in atropinized cats a marked depressor action was still obtained. It was not until the publication of the work of Best, Dale, Dudley and Thorpe<sup>2</sup> that the vasodepressor action of liver extracts could be definitely attributed to histamine and choline. These workers obtained histamine and choline as pure salts and chemically identified and physiologically assayed them.

Ever since operation was first resorted to for the relief of obstruction of the common bile duct, a certain percentage of the patients have died from a vasomotor collapse occurring some hours after the operation. Clinically, this condition has been known as "liver shock." The condition of shock which is brought on during the operation and which belongs to the realm of surgical shock in general is not included in this definition. It may be that the mechanism of this is, in certain aspects, similar to that known as "liver shock," but further than this it is not related. The exact time of appearance of the symptoms after operation varies in hours, but it always occurs after the recovery from the effects of the anesthetic and the actual surgical procedure. The condition has been observed after a variety of procedures practiced for relief of the obstruction. It occurs after the common duct has been drained with or without removal of the obstruction. It occurs after mere drainage of the gallbladder for relief of the obstruction. It has been observed after the use of general or local anesthesia. The mere relief of the increased ductal pressure suffices to cause its appearance in a definite proportion of cases. The patient is apparently doing well, when suddenly the phenomena, commonly associated under the name "shock," are exhibited.

Many explanations have been offered for its occurrence, but as yet, a fully satisfactory explanation has not been forthcoming. The explana-

tion of Ransahoff,<sup>3</sup> who believed that shocklike states during and after operations involving the common bile duct are due to sudden stretching or pulling forward of the structures in the gastro-hepatic omentum, thus constricting the portal vein, is not adequate. Although this might perhaps account for shock occurring during operation, it could not account for its appearance several hours later in a patient who previously had exhibited no evidence of it. It also fails to account for the appearance of this condition when only the gallbladder is drained, frequently under local anesthesia, and the common duct has not been handled.

Heyd<sup>4</sup> and others have, at various times, mentioned the fact that this condition is in many ways similar to anaphylactic shock, and this similarity has been observed by many writers. It was supposed that the relief of the obstruction permits the entrance into the blood stream of certain products which are toxic to the patient, but this theory does not make known the method by which sensitization of the patient takes place.

The sudden appearance of the symptoms, so similar to those seen after the injection of histamine, suggested the presence of a substance having a histamine-like action which, with the release of the obstruction, gains access to the blood stream. It seemed that, among other things, an attempt should be made to ascertain whether or not during obstruction of the duct an excess of depressor substances is formed which might, with the release of the obstruction, be liberated. This paper is concerned with this aspect of the problem.

Rous, Larimore, McMaster, Elman<sup>5</sup> and others have shown that complete obstruction of the common bile duct causes complete hepatic secretory suppression, after a variable period of time, depending on whether or not the gallbladder is functioning. In the dog, the liver continues to secrete until the pressure in the duct reaches from 280 to 330 mm. of the bile itself. At this pressure, which occurs relatively early in dogs in which the gallbladder has been removed, the hepatic parenchyma has been compressed and the portal circulation has suffered to such an extent that a marked retardation of the portal flow results.

The retardation of portal flow can be graphically illustrated in experiments in perfusion of the liver through the portal vein, during which the common duct is obstructed and free. During the period of

obstruction, the rate of perfusion will diminish as the pressure of the intrahepatic duct increases, and with the release of the obstruction an increase in the rate of perfusion occurs.

The early period at which hepatic secretory suppression occurs in animals in which the gallbladder has been removed is due to the anatomic structure of the liver. Its dense, fibrous capsule does not permit of rapid distention. In an organ composed mainly of cells as the liver is, there is not sufficient space for extensive expansion when the ducts are occluded without encroachment on the parenchyma and the vascular bed.

The increased intra-acinar pressure causes damage to the liver cells, but the portal retardation contributes still further to this and may be the more important factor. Rous and Larrimore<sup>6</sup> have shown the effect of portal retardation in rabbits. In these animals, replacement of the damaged parenchyma with connective tissue occurs within a relatively short time, while in the dog and in man this is long delayed; in them we have found a progressive parenchymal degeneration resulting in death, as a rule, before extensive cirrhosis appears.

It may be that damage to the cells either liberates certain toxic substances or further elaborates them, or that the cells store these and the restoration of the normal blood flow carries them out of the damaged cells into the circulation. This theory is based on the knowledge that "hepatic shock" is not observed in a patient as long as the obstruction in the common duct exists, but occurs only after the release of the obstruction. Whether during the period of obstruction the liver stores the substances through an inability to detoxify or excrete them, or whether they are the result of cell destruction is questionable.

In the discussion of their work, Best, Dale, Dudley and Thorpe wrote as follows:

Histamine being either present as such in the living cell, or released therefrom at the moment of death, questions of great interest arise as to the manner in which it is held by the protoplasm during life, and prevented from producing its intense physiological action. It may be there only potentially, in the form of some inactive precursor. On the other hand, it is conceivable that histamine is present as such in the cell interior, being prevented from leaving it so long as the cell membrane is physiologically intact, and that it produces its action only if some stimulus or injury causes its escape into the extra-cellular fluids. On these points we have no evidence, and it may be very difficult to obtain it.

The release of the obstruction of the duct relieves the portal stagnation which has existed, abundant evidence of which is seen in attempts to form a collateral circulation. The liver cells, already severely damaged, are subjected to a rapidly increasing hyperemia and a more gradually increased portal flow after the initial effects of the hyperemia have

---

6. Rous and Larimore: J. Exper. Med. 31:609, 1920

disappeared. In some cases this is delayed for several hours, depending on how rapidly the liver empties itself of the stagnant bile, "white" or otherwise, which is pent up in the dilated bile ducts. Pathologic examination of the liver of patients who have died from "liver shock" shows extensive cell injury and evidences of varying degrees of autolysis.

#### EXPERIMENTS

Five healthy dogs were operated on in the Laboratory of Surgical Research of the University of Edinburgh. The common duct was ligated doubly and divided between the ligatures, the distal end of the duct being buried so as to preclude any reformation of the duct continuity. The gallbladder was then removed. The anesthetic used was ether, and careful aseptic technique was practiced. After operation the dogs were kept on the routine laboratory diet, consisting of carbohydrates, protein and a salt mixture. They were killed at varying periods. The liver was immediately chopped into small pieces and placed in 95 per cent alcohol. There was no chance of contamination, and at no time did more than five minutes elapse between removal of the liver and the placing of it in alcohol. This precluded any changes occurring in the liver tissue after death, even though Best, Dale, Dudley and Thorpe<sup>3</sup> stated that "we have found no evidence that the proportion of free histamine increases in the period immediately following the death of the animal." The same procedure was carried out in the extraction of normal liver tissue.

The process of extraction was exactly like that reported by these observers.

I report the complete protocols of dog N2 and dog J5. Although the actual percentages varied considerably, we demonstrated a greater amount of depressor substances in the jaundiced liver tissues in every extraction than is found in normal liver tissue. If my hypothesis is correct, it would seem that this should be true since "hepatic shock" does not occur after the release of every obstruction of the common bile duct. The difference is one of degree and, no doubt, a larger number of extractions would have shown even wider variations.

#### PROTOCOLS

EXPERIMENT 1.—Dog J1 was operated on, July 5, 1927, under ether anesthesia. The common duct was divided between ligatures, and a cholecystectomy was performed. Recovery from the operation was satisfactory. On July 8, the van den Bergh reaction was: direct, immediate; indirect, 3.5 units. These stools were clay colored. On July 13, while the animal was under ether anesthesia, the liver was removed. On the same day, the liver was removed from dog N1.

One hundred and forty grams of normal liver and an equal amount of liver in which the bile duct had been obstructed were immediately minced and placed in flasks holding 350 cc. of 95 per cent alcohol. Each container was put in a shaker for thirty minutes and then allowed to stand for eighteen hours. The fluid was decanted off and filtered and the precipitate washed with 285 cc. of 60 per cent alcohol, which was then placed in the flasks containing the liver substance. Each flask was again shaken for thirty minutes and the fluid removed and filtered.

To the extract of normal liver was added 0.9 cc. of sulphuric acid, and to the extract of jaundiced liver 1 cc. of sulphuric acid to prevent foaming. The extracts

were separately concentrated in vacuo, the first to 80 cc. and the second to 100 cc. Each was filtered, washed and made up to 140 cc., so that 1 cc. of the extract equaled 1 Gm. of the liver substance.

These extracts were sterilized in an autoclave and then made up in dilutions with sterile saline solution and put in ampules which were kept in a cool place.

On July 15, 1927, with assistance of Dr. Dryerre, an experiment was performed on a cat. The results of the experiment are shown in figure 1. Ether anesthesia was used. The vagi were sectioned. Extracts of jaundiced and nonjaundiced liver were injected into the external jugular vein. The injections were not timed. The blood pressure was taken from the carotid artery.

It seems from the tracings shown in figure 1 that there is an excess of depressor substances in the jaundiced liver tissue.

Each extract was then reextracted with alcohol in a Soxhlet apparatus (10 cc. of each being placed on Schleitter and Shüll's strips and dried). The alcohol extract was evaporated on a waterbath and then treated with 10 cc. of physiologic solution of sodium chloride. The undissolved residue, which was fatty in character, was dissolved in 2 cc. of 95 per cent alcohol and 8 cc. of physiologic solution of sodium chloride. It went readily into solution. The residue in the thimble was now extracted with distilled water, evaporated to about 3 cc., and made up to

Fig. 1.—Tracings showing the extent of arterial depression caused by extract from jaundiced (J.L.) and normal (N.L.) liver.

10 cc. with physiologic solution of sodium chloride. The various fractions were then put in ampules as before.

One cubic centimeter of each fraction represented that portion of 1 Gm. of the liver substance. The solutions were marked as follows:

N.A.R. = Evaporated alcoholic extract (normal liver tissue) in saline solution.

N.A.A.R. = Residue of evaporated alcoholic extract insoluble in water dissolved in 2 cc. alcohol and 8 cc. saline solution.

N.W.R. = Water extract from thimble evaporated and taken up in saline solution.

The extracts of jaundiced liver were similarly marked, except that J is substituted for N.

On July 20, 1927, another experiment was performed on a cat in the same manner as before. The results of the experiment are shown in figure 2. Ether anesthesia was used. The vagi were cut. The blood pressure was taken from the carotid artery. Injections were made into the external jugular vein.

It would appear that in the alcoholic (A.R.) portion of the extracts, we obtained a distinct difference in the depression of the blood pressure. In the residue of the evaporated alcoholic extract (A.A.R. fractions) there was no appreciable difference, while the water extract from the thimbles (W.R. fractions) showed a slightly greater depression in the J.W.R. portion.

The A.R. fraction injections were followed by a pressor effect after the recovery from vascular depression.

EXPERIMENT 2.—Dog J2 was subjected to a similar operation and was killed on July 28, 1927. The extraction was carried out through the precipitation of depressor substances with phosphotungstic acid and decomposition of the phosphotungstate by grinding with an excess of baryta in water at 60 C. The procedure was exactly like that reported by Best, Dale, Dudley and Thorpe.

The experiment shown in figure 3 was performed on a cat on Aug. 8, 1927, under ether anesthesia. The vagi were cut. The blood pressure was taken from the carotid artery. Injections were made into the external jugular vein.

It will be seen that the extracts of both of the jaundiced animals caused a greater depression of blood pressure than normal liver extract. The variation in the amount of depressor substance between J.L.E. no. 1 and J.L.E. no. 2 is definite. This variation was common in all extractions from jaundiced animals.

EXPERIMENT 3.—On Aug. 29, 1927, dog J5 was operated on under ether anesthesia. A right rectus incision was made; the common duet was ligated and divided, and cholecystectomy was performed.

On Sept. 11, 1927, the dog was etherized and the abdomen opened. The common duet was dilated and a small amount of free bile-stained fluid was present in the peritoneal cavity. The liver was removed and the animal killed.

Fig. 2.—Tracings showing the effect of intravenous injections of saline solutions of alcohol extracts and alcohol residue extracts of normal and jaundiced liver in the anesthetized cat. N.A.R. is the evaporated alcoholic extract (normal liver tissue) in saline solution; N.A.A.R., residue of evaporated alcoholic extract insoluble in water dissolved in 2 cc. alcohol and 8 cc. saline solution; N.W.R., water extract from thimble, evaporated and taken up in saline solution. The extracts for jaundiced liver are similarly marked, except that J is substituted for N.

One hundred and fifty grams of liver was immediately minced and immersed in 95 per cent alcohol. Extraction was then begun as before. The extracts were evaporated down to from 30 to 50 cc. each time so that the working solutions were much less than in previous extractions. No difficulties were encountered. The precipitation with phosphotungstic acid (Kahlbaum) in sulphuric acid was immediate and of considerable amount. The phosphotungstates were ground in an excess of baryta at 60 C. and, after the baryta was disposed of, the solutions were neutralized and sterilized and put in sterile ampules which were kept in a cool place.

On Sept. 14, 1927, I removed 150 Gm. of liver from Dog N2 under ether anesthesia. The animal was then killed. Extraction was carried out by a procedure identical with that used for dog J5.

After extraction of the solutions as phosphotungstates and their decomposition with baryta and their being freed of the latter with sulphuric acid and neutralization, they were evaporated to about 25 cc. and made up with distilled water to 50 cc. each, so that 1 cc. of each extract equaled 3 Gm. of liver substance.

On Oct. 6, 1927, the extracts from dogs J5 and N2 were standardized at the National Institute for Medical Research. An experiment (Dr. Gaddum assisting) was performed on a cat under ether anesthesia. The blood pressure was taken from the carotid artery. Injections were made into the saphenous vein. The injections were timed. Each extraction was washed in 2 cc. of physiologic solution of sodium chloride. The results of the experiment are shown in figure 4. N.L.E. indicates normal liver extract; J.L.E., jaundiced liver extract; N.L., normal liver, and J.L., jaundiced liver.

Fig. 3.—Comparison of normal liver extract and jaundiced liver extract from the first (J1) and second (J2) jaundiced dogs. The extracts were extracted with alcohol, evaporated in vacuo and taken up with saline solution. In this figure and in figures 4, 5, 6 and 7, N.L.E. indicates normal liver extract and J.L.E., jaundiced liver extract.

In this experiment we found that:

0.15 cc. N.L.E. = 0.003 mg. Histamine Base

0.1 cc. N.L.E. = 0.002 mg. H.B.

1 cc. N.L.E. = 0.02 mg. H.B.

1 gram N.L. = 0.00666 mg. H.B.  
 0.075 cc. J.L.E. > 0.15 cc. N.L.E.  
 0.1 cc. J.L.E. > 0.3 cc. N.L.E.  
 0.3 cc. N.L.E. = 0.075 cc. J.L.E.  
 1 cc. N.L.E. = 0.02 mg. H.B.  
 1 cc. J.L.E. = 0.08 mg. H.B.  
 1 Gm. N.L. = 0.00666 mg. H.B.  
 1 Gm. J.L. = 0.026 mg. H.B.

From the tracings shown in figure 4, I would conclude that 1 Gm. of normal liver contains the equivalent of 0.00666 mg. of histamine base, while 1 Gm. of jaundiced liver contains the equivalent of 0.026 mg. of histamine base. Thus, in this extraction (J5) the liver contains four times the amount of depressor substances present in the normal liver extraction (N2).

Fig. 4.—Series of tracings taken to estimate the depressor effect of normal liver extract and jaundiced liver extract, histamine being used as a standard.

The extracts were then standardized on the virgin uterus of the guinea-pig. Since choline does not produce uterine contraction while histamine does, this method seemed to afford a double check. First, it would tell whether or not histamine was present in the extract and, second, it would afford a method for estimating the difference in concentration of histamine and choline after comparison with the blood pressure tracings.

In the experiment on the uterus of the guinea-pig on Oct. 7, 1927 (with the cooperation of Dr. H. H. Dale), and in the subsequent experiment, we used the uterus bath as described by Dale. The effect of the extract is shown in figure 5. The bath was kept at a constant temperature, 38 C., and the preparation was thoroughly washed after each contraction. It was found that 0.003 mg. H.B. = 0.1 cc. N.L.E. This may not be quite accurate since later, 0.1 cc. N.L.E. < 0.003 mg. H.B. However, 0.1 cc. J.L.E. is much greater than 0.1 cc. N.L.E.

At a subsequent experiment, we obtained the tracing shown in figure 6. In this experiment, we found that 0.1 cc. N.L.E. is not quite as great as 0.003 mg. H.B., and 0.05 cc. J.L.E. is about equal to it, while 0.025 cc. J.L.E. is not as great. It

was also found that: 0.05 cc. J.L.E. = 0.003 mg. H.B.; 1 cc. J.L.E. = 0.06 mg. H.B., and 1 cc. N.L.E. < 0.03 mg. H.B.

From the experiments so far conducted, the following conclusions may be drawn from the effect on blood pressure and on the uterus: On blood pressure, 1 cc. J.L.E. = 0.08 mg. H.B. On the uterus, 1 cc. J.L.E. = 0.06 mg. H.B. On blood pressure, 1 cc. N.L.E. = 0.02 H.B. On the uterus, 1 cc. N.L.E. < 0.03 mg. H.B.

It would appear from this that perhaps the ratio of histaminic and choline in the two as extracts is not the same and that, while the ratio from blood pressure tracings before atropine is given makes J.L.E. nearly four times as strong as N.L.E., on the uterus this ratio is only about  $2\frac{1}{2}:1$ .

It is well known that choline does not exhibit its action on blood pressure in the atropinized cat. It was therefore thought advisable to conduct such an experiment in an effort to standardize our extracts more accurately.

Figure 5

Figure 6

Fig. 5.—Effect of extract on virgin uterus of guinea-pig.

Fig. 6.—Effect of extracts on virgin uterus of guinea-pig.

On Oct. 11, 1927, an experiment was performed on a cat under ether anesthesia. The blood pressure was taken from the carotid artery. Injections were made into the saphenous vein; they were timed and followed with injections of 2 cc. of physiologic solution of sodium chloride. Ten milligrams of atropine was given before operation (Ravdin and Gaddum). The results of the experiment are shown in figure 7.

This tracing offers a good check against the action of the extract on blood pressure before atropinization and on activity of the uterus. Here we found that:

0.003 mg. H.B. = 0.075 cc. J.L.E. after atropine was given.

0.003 mg. H.B. < 0.075 cc. J.L.E. before atropine was given.

After atropine, 0.004 mg. H.B. = 0.25 cc. N.L.E.

Before atropine, 0.003 mg. H.B. = 0.15 cc. N.L.E.

Before atropine, 0.3 cc. N.L.E.  $\equiv$  0.075 cc. J.L.E.

Ratio, 1:4.

After atropine, 0.25 cc. N.L.E.  $>$  0.075 cc. J.L.E.

Ratio, 1:2½.

The difference in the effect of the extracts before and after atropinization may be due to an excess of choline in J.L.E. This seems entirely logical, for the checks on activity of the uterus against extract action in an atropinized animal are satisfactory. From the blood pressure tracings, it would appear as if there is an excess of choline over and above the excess histamine in J.L.E., since its equivalent is reduced (in terms of histamine base) 50 per cent after atropine is given, while N.L.E. is reduced only 20 per cent.

Fig. 7.—Effect of the extracts (J5 and N2) on the blood pressure of the cat after atropinization.

These conclusions are drawn from the following figures taken from the tracings shown in this paper. Before atropine was given, the effect of J5 and N2 on the blood pressure was:

1 cc. J.L.E.  $\equiv$  0.08 mg. H.B.

1 cc. N.L.E.  $\equiv$  0.02 mg. H.B.

Ratio, J.L.E.  $\equiv$  N.L.E. :: 4:1.

After the administration of atropine, which abolished the action of choline:

1 cc. J.L.E.  $\equiv$  0.04 mg. H.B.

1 cc. N.L.E.  $\equiv$  0.016 mg. H.B.

Ratio, J.L.E.  $\equiv$  N.L.E. :: 2½:1.

The excess of depressor substances which has been demonstrated in jaundiced liver tissue may offer an explanation for certain of the "shocklike" states occurring after operations for the relief of obstruction of the common bile duct. At the time of reestablishment of the

portal circulation, these depressor substances may be "washed" into the blood stream and then exhibit their violent action. In several of the patients who have died following "liver shock," we have demonstrated varying degrees of cell autolysis. It may be that from these dead cells histamine and choline are released. We have studied the effect of dextrose on cell protection, and the well known advantages of intravenous injections of dextrose in preventing so-called liver shock will be given in a later contribution.

#### SUMMARY

1. A study of vasodepressor substances in the liver after obstruction of the biliary duct is presented.
2. There is an increase of both histamine and choline in this tissue over that found in normal liver.
3. This increase of depressor substances may account for the occurrence of so-called liver shock after operations for the release of obstruction of the common duct.

# EXPERIMENTAL PERITONITIS AND PERITONEAL IMMUNITY\*

SIEGFRIED F. HERRMANN, M.D.

*Fellow in Surgery, the Mayo Foundation*

ROCHESTER, MINN.

Whenever the bowel must be incised or resected, absolute asepsis cannot be maintained, and peritonitis is still a relatively common post-operative complication. New methods of preventing peritonitis must be developed. Experimental investigation in this field has been greatly hampered by the difficulty of producing peritonitis experimentally. No one has yet been able to reproduce at will a uniform type of peritonitis comparable to the clinical condition as it occurs in man. Obviously, when the fundamental factors on which the development of a disease depends are so little understood, one may expect little progress in its prevention. My experiments were undertaken for the purpose of investigating these fundamental factors. My original purpose was to study the causes of death in peritonitis. It soon became apparent, however, that an understanding must first be gained of the factors by which experimental peritonitis may be produced. This study then led to a consideration of the defensive reactions which are associated with recovery after bacterial or fecal soiling of the peritoneum.

A review of previous work leads to confusion. Most reports indicate that attempts to produce experimental peritonitis by intraperitoneal injections of bacteria, or by fecal soiling, are unsatisfactory. If virulent germs are used, the experimental animals die, but peritoneal reaction may be entirely absent. Various injuries to the peritoneum in addition to infection, section of the bowel, artificial ileus or the introduction of foreign materials make the development of peritonitis more certain. I avoided such methods because I wished to study bacterial peritonitis in pure form.

In the first series of rabbits, varying amounts of suspension of dog feces were injected intraperitoneally. In most cases such injections failed to produce visible exudative peritonitis. Small doses were well tolerated. Large doses killed the rabbits, but practically the only peritoneal change was marked hemorrhagic reaction in the serosa of

\* Submitted for publication, Sept. 17, 1928.

\* Abridgment of thesis submitted to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the degree of Ph.D. in Surgery. Work done in the Division of Experimental Surgery and Pathology, the Mayo Foundation. Preliminary report published in Proc. Staff Meetings of the Mayo Clinic 3:21 (Jan. 25) 1928.

the cecum. General fibrinous exudation was observed only occasionally. Attempts at modifying the virulence of the fecal flora by incubation with rabbit's blood, or the simultaneous injection of blood, were also unsatisfactory. The rabbits then died more consistently, but necropsy did not show peritonitis. Results with injections of feces from human beings were identical.

As attempts to vary the size of the infecting dose and the virulence of the bacteria proved to be unsatisfactory, I decided to try influencing the other variable factor in infection, the resistance of the animal. In the few instances in which intraperitoneal fecal injections produced peritonitis, the rabbits may have been more resistant; thus, peritonitis may be regarded as a defensive reaction. Any reaction of defense depends on the presence of immunity. It seemed logical to try to raise the immunity before the introduction of the infective material.

A series of rabbits was immunized by intraperitoneal injections of a heated broth culture containing *Bacillus coli* and *Streptococcus viridans*. This mixture was employed because it was repeatedly isolated from the heart blood of rabbits that died after the intraperitoneal injection of feces. After several such immunizing injections, living cultures of the same bacteria were injected intraperitoneally into these rabbits, and into fresh controls. The controls died quickly without showing evidence of peritonitis. Certain of the immunized rabbits also succumbed, but necropsy showed definite fibrinous or fibrinopurulent peritonitis in almost every case. Some of the rabbits survived the first injections of living cultures and then received larger doses of freshly isolated cultures. The peritoneum also reacted with definite peritonitis. Some of the rabbits died and some survived. In general, the degree of peritonitis found in the surviving rabbits when they were killed was greater than in those that died early. Similar results were obtained with another series in which pure cultures of colon bacilli were used.

It would appear, therefore, that the development of bacterial peritonitis depends on immunity. It is a defensive tissue reaction. An unimmunized control rabbit dies soon from acute sepsis. The immunized rabbit, by reason of his immunity, shows a reaction in the form of peritonitis, survives longer than the control and may recover. It is further conceivable that if the degree of immunity greatly overbalances the size of the dose injected and the virulence of the organisms, visible peritoneal reaction will not result. Thus, partial immunity leads to peritonitis, while complete or perfect immunity prevents it.

Besredka's<sup>1</sup> conceptions of local immunity suggest the idea that the form of immunity which determines peritonitis is a local immunity of

---

1. Besredka, A.: Local Immunization; Specific Dressings, Baltimore, Williams & Wilkins Company, 1927, p. 178.

the tissue of the peritoneum rather than a general humoral reaction. That there may be such a thing as local immunity of a serous membrane is supported by an observation of Gay.<sup>2</sup> He found that the intrapleural injection of streptococci into rabbits gave some protection against subsequent intrapleural injections, but not against intravenous injections. I have made several observations which indicate local immunity of the peritoneum. These observations may be summarized in the statement that intraperitoneal injections of vaccine give greater protection against subsequent intraperitoneal injections of lethal doses of bacteria than do preliminary subcutaneous or intravenous injections of vaccine. This is true despite the observation that the humoral antibody response, as measured by the agglutinin titer, is least after intraperitoneal injections. Thus, the average agglutinin titer after three intravenous injections of vaccine of colon bacilli was  $+1:900$ , after three subcutaneous injections it was also  $+1:900$ , and after three intraperitoneal injections it was  $+1:275$ . The following experiment illustrates the comparative protective effect of subcutaneous and intraperitoneal vaccination, and will serve to emphasize again the defensive nature of peritonitis.

#### METHOD

Six rabbits were given injections of vaccine of colon bacilli. Three received 1 cc., diluted in 5 cc. of sodium chloride solution, subcutaneously, and three received the same amount intraperitoneally. The dose was repeated two days later. Agglutinin titers were not determined as in previous experiments, but the test injection of living bacteria was given early, three days after the second vaccination, or five days after the first, before there could be any question of a considerable general antibody response. All the rabbits, and three unvaccinated controls, then received intraperitoneally 10 cc. of a twenty-four hour dextrose broth culture of the same strain of colon bacillus after its virulence had been restored by passage through rabbits. One hour after this injection, 4 drops of blood were collected aseptically from the marginal ear vein of each rabbit into tubes of melted agar, cooled to 45 C., and plates poured (table 1).

#### RESULTS

Definite bacteremia from colon bacilli manifested by more than seven colonies an hour after the intraperitoneal injection is invariably fatal. The rabbits die rapidly, without peritonitis and with positive cultures of the heart blood at necropsy. If the blood is not flooded with numerous bacteria, the rabbit survives. Necropsy of such surviving rabbits shows the presence of peritonitis. It seems logical to regard this as a defensive reaction of the peritoneum, the purpose of which is localization of the infection within the abdomen. Peritonitis thus enables the rabbit to survive and escape bacteremia. That this defensive reaction of the peritoneum depends on local immunity is attested by the fact that two of three rabbits vaccinated intraperitoneally survived, while of those vacci-

---

2. Gay, F. P.: On Local and General Immunity, *J. Immunol.* 8:1, 1923.

nated subcutaneously, and of the controls, two of three died, and did not show peritoneal reaction. In the case of one rabbit, intraperitoneal vaccination apparently failed to produce sufficient immunity. The peritoneal barrier was not sufficient to prevent the early flooding of the system with bacteria. That the defensive forces rallied somewhat is indicated by survival for twenty-four hours, and the finding of slight peritonitis and sterile blood at necropsy.

Two animals vaccinated subcutaneously died sooner than the controls. That one of this group survived must be ascribed to a natural variation in immunity, just as in the control group.

TABLE 1.—*Comparative Protective Effect of Subcutaneous and Intraperitoneal Vaccination*

Rabbit		Method of Vaccination	Colonies in Four Drops of Blood	Result	Necropsy Data	Culture of Heart Blood
Sex	Weight, Gm.*					
F	1,730	Subcutaneous	Three	Survived forty-eight hours; killed	Slight fibrinous peritonitis of omentum; otherwise negative	Negative
F	1,900	Subcutaneous	Innumerable	Died after one and a half hours	Negative	Colon bacilli
R	1,720	Subcutaneous	Many	Died after one and one-fourth hours	Negative	Colon bacilli
F	1,490	Intraperitoneal	Five	Survived forty-eight hours; killed	Numerous fibrinous lumps on omentum, liver, spleen, and less on mesentery	Negative
F	1,500	Intraperitoneal	None	Survived forty-eight hours; killed	Definite fibrinous peritonitis of omentum	Negative
F	1,770	Intraperitoneal	Innumerable	Died after twenty-four hours	Slight fibrinous reaction of omentum	Negative
F	1,810	(Control)	Innumerable	Died after seven hours	Negative	Colon bacilli
M	1,950	(Control)	Sixty	Died after seven hours	Negative	Colon bacilli
F	1,450	(Control)	Seven	Survived forty-eight hours; killed	Small fibrinous lumps on omentum and diaphragm	Negative

\* Weights are recorded merely to show that slight variations in weight do not signify proportionate degrees of resistance. Animals of approximately the same weight were used. When there was a variation the heavier rabbits were used as controls.

I have indicated that survival after intraperitoneal infection does not apparently depend on general immunity as measured by the height of the agglutinin titer. It must be granted that the agglutinin titer is not a true or complete measure of humoral resistance; however, in animals recently given immunizing injections, it should be an indicator of the concentration of antibodies in the blood. The increase in agglutinins should parallel the increase in other antibodies. This experiment, performed before any considerable general antibody increase would occur, gives further indication of the presence of local, rather than general, immunity.

A sterile blood culture, after an intraperitoneal injection of bacteria, may mean either that bacteria are not entering the blood stream, because of an effective peritoneal barrier, or that they are rapidly destroyed as soon as they enter the blood. In these experiments the former interpretation is given, for the following reasons: 1. The concentration of humoral antibodies, as measured by the agglutinin titer does not bear any relation to the question of survival after intraperitoneal infection. 2. Intraperitoneal immunizing injections give greater protection against subsequent lethal doses of bacteria injected intraperitoneally than do subcutaneous or intravenous injections. 3. Sterile, or nearly sterile, cultures of blood are usually associated with definite fibrinous peritonitis, which I interpreted as a defensive reaction, because rabbits showing this peritonitis are much more likely to survive than those showing definite bacteremia.

I believe, therefore, in the presence of a factor of local peritoneal immunity, and that this immunity, against a specific bacterium such as the colon bacillus or the streptococcus, can be enhanced by intraperitoneal inoculation of the specific organism. Operative soiling of the peritoneum with intestinal contents offers a much more complex problem, but the following accidental observation indicated the possibility of immunizing the peritoneal cavity against fecal soiling.

Four rabbits survived intraperitoneal injections of large doses (15 cc. of a twenty-four hour dextrose broth culture) of colon bacilli. I believed that these rabbits might serve for the isolation of fecal pathogens other than colon bacillus because, if injected with a suspension of feces, they might inhibit the growth of the colon bacillus and succumb to other possible pathogenic components of the fecal flora. Each rabbit was accordingly injected intraperitoneally with 5 cc. of a suspension of fresh dog feces. Four control rabbits were similarly injected. To my surprise, none of the previously injected animals died, while three of the control animals succumbed.

These results suggested that previous peritoneal infection with colon bacilli may protect against later fecal soiling, and further indicated the possibility of artificially protecting the peritoneum against such soiling by the use of vaccine. I have shown that the peritoneal resistance against colon bacilli or a combination of streptococci and colon bacilli, can be raised by repeated intraperitoneal injections of these organisms. The question now arose whether immunization with these organisms might also protect against subsequent contamination by the entire fecal flora.

#### SURVEY OF THE LITERATURE

A search of the literature revealed records of various attempts to immunize the peritoneum. The earliest work was that of Issaëff,<sup>3</sup>

---

3. Issaëff: Untersuchungen über die künstliche Immunität gegen Cholera. Ztschr. f. Hyg. u. Infektionskrankh. 16:287, 1894.

Solieri<sup>4</sup> and Miyake.<sup>5</sup> The principle established was that the production of intraperitoneal leukocytosis by the use of various irritants gave protection against subsequent peritoneal infection. This idea was applied to clinical practice by von Mikulicz.<sup>6</sup> Injections of sodium nucleinate, which produced hyperleukocytosis, were given preoperatively in his clinic for several years. The intraperitoneal administration of this drug led to such severe reactions that it was given subcutaneously, and it was believed that the same protective effects were obtained. Several enthusiastic reports were published by various surgeons, but it remained for Aschner and von Graff,<sup>7</sup> working in von Eiselsberg's clinic, to arrive at a proper critical evaluation of this subject. They showed that the surgical mortality was not influenced by this method of preoperative preparation.

Nature's method of raising the general peritoneal resistance was pointed out by Moszkowicz.<sup>8</sup> He noted that perityphlitic abscess could be operated on with relative safety, and that operative breaking down of adhesions seldom led to general peritonitis. The adjacent infection prepares the general peritoneum so that it is more reactive and more resistant. This is another way of saying that rapid perforation of the bowel is much more likely to be fatal than slowly developing abscess which gives the general peritoneum time to mobilize its defensive forces. It is not unlikely that in this process a factor of specific immunization may play a part along with the general irritative reaction.

An observation made by London<sup>9</sup> should be mentioned in connection with the natural process of peritoneal immunization. He noticed that dogs that had undergone operation on the bowel were definitely more resistant in subsequent abdominal operations. Such dogs tolerated intra-abdominal angiostomy very well, while the mortality was 100 per cent if this procedure was attempted as a primary operation. It seems logical

to assume that the slight soiling with bowel contents occurring at the first operation made the peritoneum more resistant, and one wonders whether the lowered mortality of two-stage operations for resection of the colon may not be due, in part at least, to such a factor.

Of passing interest is the theory proffered by Dudgeon and Sargent<sup>10</sup> in 1905. They ascribed great protective power to the presence intraperitoneally of an avirulent form of *Staphylococcus albus*. If its invasion precedes that of the colon bacillus, or other pathogens, a defensive purulent exudate is called forth which makes the prognosis much more favorable. They found experimentally that guinea-pigs could be protected against colon bacilli by the previous intraperitoneal inoculation of this coccus. Apparently, this suggestion has never been taken up by other experimenters.

Gál<sup>11</sup> recently published results of experiments which in his opinion indicate that the colon bacillus and its products may play an important part in the defense against peritoneal infection. He vaccinated guinea-pigs, usually subcutaneously, with an autolysate of the colon bacillus, and found that this led to an increase in intraperitoneal leukocytosis and greater phagocytosis of typhoid bacilli than in unvaccinated controls. There was evidence of protection against lethal doses of typhoid bacilli, and also against the fecal soiling of experimental intestinal perforation. Autolysates of streptococci or staphylococci had no such effect. He therefore credited the antigen of the colon bacillus with the property of exciting specific intraperitoneal leukocytosis, particularly through the agency of the omentum. There was neither general peripheral leukocytosis nor an increased bactericidal power of the blood.

Steinberg and Goldblatt<sup>12</sup> also reported protective effects of inoculation of colon bacilli. Dogs so vaccinated survived the subsequent intraperitoneal injection of tragacanth and colon bacilli, or of fecal material. This protection is ascribed to increased general immunity.

These various reports show clearly that experimentally peritoneal resistance can be raised by prophylactic intraperitoneal injections of various substances, because of the ensuing irritative, nonspecific defense reaction and local leukocytosis. Subcutaneous injections, however, although they lead to general leukocytosis, probably do not protect against peritoneal soiling, unless the recent claims for colon bacilli can be substantiated. In order to make clinical use of the experimental data, it

would be necessary to devise a method of safe intraperitoneal prophylaxis. The ideal substance to be used for such injections would be one which not only arouses nonspecific defensive forces, such as hyperemia and leukocytosis, but leads to specific local immunity against the pathogenic bacteria inhabiting the intestinal tract. The frequent recovery of a culture of streptococcus and colon bacilli from the heart blood of rabbits dying soon after intraperitoneal injection of feces suggests that these organisms may be the most important pathogens of feces. Experiments were therefore planned to determine whether a vaccine of these bacteria could be used to bring about the desired protection. I am fully aware that there are many different strains of colon bacilli and enteric streptococci, more or less distinct immunologically. It would be impossible to be sure that all of them were included in a vaccine. Yet it seems probable that a strain of proved invasive powers, proved by the manner of isolation, might serve to give protection against the entire related group.

#### EXPERIMENTAL ATTEMPTS

My experimental attempts to immunize the peritoneum against fecal soiling may be divided into several groups: (1) intraperitoneal immunization with colon bacilli; (2) intraperitoneal immunization with a vaccine of streptococci and colon bacilli; (3) antiviral experiments, and (4) comparison of cultures of heart blood of rabbits after the injection of dog feces intraperitoneally.

*Intraperitoneal Immunization with Colon Bacilli.*—Rabbits were immunized by two intraperitoneal injections of virulent colon bacilli. Immunity to the bacilli was proved by injecting a fresh virulent culture in a dosage sufficient to kill a control animal in two hours. Three or four days later, the rabbits were given 5 cc. of a suspension of fresh dog feces intraperitoneally. Seventy-five per cent of the immunized rabbits survived, but 33 per cent of the controls recovered. The actual protective value of immunization with colon bacilli against fecal soiling must be slight. Large doses (usually one agar slant) of colon bacilli were employed; while the dose of feces was not sufficient to kill more than two thirds of the controls, a dose sufficiently potent to kill controls uniformly would certainly have lowered the percentage survival of the immunized animals. Some degree of resistance is indicated by the fact that the experimental animals reacted with definite peritonitis, while controls died of bacteremia with little peritoneal change. As has been shown, this is probably evidence of local immunity.

*Intraperitoneal Immunization with a Vaccine of Streptococci and Colon Bacilli.*—The vaccine was prepared by inoculating a flask of dextrose broth with the mixed culture of streptococci and colon bacilli obtained from the heart blood of a rabbit after an intraperitoneal injection.

tion of dog feces. After the broth had been incubated forty-eight hours, it was centrifugalized, and the broth was poured off in order to eliminate soluble toxic substances. After the sediment had been washed with sterile sodium chloride solution, it was recentrifugalized and then made up to 120 cc., the original volume, with physiologic solution of sodium chloride. This suspension was then heated at 65 C. for half an hour.

Rabbits were given intraperitoneal injections with 1 cc. of vaccine in 5 cc. of physiologic solution of sodium chloride, and again, three days later, with 2 cc. After two days, all received intraperitoneally 5 cc. of a suspension of fresh dog feces.

Of the rabbits so immunized, 80 per cent survived; all the controls died. It was again noted that the immunized animals had definite peritonitis, and that the controls almost always died without peritoneal reaction.

When I used only one injection of vaccine, protection was not conferred. This argues against simple nonspecific irritation as an explanation for previously noted protective effects. If two injections of vaccine give protection when one does not, it seems logical to assume that some specific immune factor other than hyperemia and leukocytosis has developed.

Further evidence of local peritoneal immunization rather than a general systemic effect of vaccines is shown by experiments in which parallel series of rabbits are inoculated subcutaneously and intraperitoneally. Doses of 1 cc. and 2 cc., respectively, in 5 cc. of sodium chloride solution were given at two day intervals, and 5 cc. of a suspension of fresh dog feces was injected intraperitoneally two days after the last dose (table 2).

The only definite protection occurred in the rabbits receiving the vaccine of streptococci and colon bacilli intraperitoneally. Two of them remained normal and one survived eight days; that this rabbit was resistant was attested by the marked peritonitis present.

At first glance, it appears as if the vaccine of subcutaneous colon bacilli also afforded high protection. The survival of two of this group can, however, hardly be ascribed to a protective effect, since one of the group showed utter lack of resistance, dying in four hours, much earlier than the controls. It must also be noted that subcutaneous combined vaccine of streptococci and colon bacilli did not afford protection. One would reasonably expect it to accomplish as much, if not more, than the vaccine of colon bacilli only. I believe it is probable, therefore, that these two rabbits were naturally resistant, and would have survived without vaccine.

Such results, taken with those of other experiments, would seem to establish the high protective effect of intraperitoneal inoculation with the

vaccine of streptococci and colon bacilli. Subcutaneous inoculations of this vaccine are of no value, and possible benefits of vaccine of colon bacilli only are questionable.

In several other experiments, I attempted to determine whether or not subcutaneous vaccination with colon bacilli afforded protection

TABLE 2.—*Comparative Protective Effect of Subcutaneous and Intraperitoneal Vaccination Against Fecal Soiling of the Peritoneum*

Rabbit		Method of Vaccination	Result	Necropsy Data	Culture of Heart Blood
Sex	Weight, Gm.*				
M	1,530	Subcutaneous (colon bacilli)	Died after four hours	Peritoneum normal	Streptococci and colon bacilli

\* The weight of the rabbit is given in this protocol in order again to demonstrate that moderate variations in weight are not a factor in resistance.

against the intraperitoneal injection of feces. In none of them could I demonstrate satisfactorily a protective effect.

Many of my experiments had to be discarded as worthless, because I was not always able to so gage the dosage of vaccine and of feces that conclusions could be drawn from the results. Too large a dose of vaccine, especially intraperitoneally, may actually weaken the rabbit and lower his resistance. This objection was met by adhering to doses of

from 1 to 2 cc. Various samples of feces are of different virulence. I always used 5 cc. of an approximately 5 per cent suspension. Sometimes this amount contained many times a lethal dose so that all controls and experimental animals rapidly succumbed. Such experiments were worthless because the degree of protection conferred by vaccines is only relative. Only those experiments have been reported in which a distinct difference could be observed between controls and experimental animals.

As a further test of intraperitoneal vaccination with streptococci and colon bacilli, the procedure was applied to surgical procedures on the dog. Resection of the colon was carried out without attempting to prevent fecal soiling. Although the number of dogs was too small to be conclusive, the results indicate protection. Apparent failures could be ascribed to technical errors, for necropsy in these cases showed leaking anastomoses. An adequate blood supply had not been preserved, so that a gangrenous slough occurred. Vaccination protected against operative soiling, but obviously not against the constant soiling from a leaking gangrenous suture line.

*"Antivirus" Experiments.*—Stimulated by the work of Besredka, I attempted to immunize the peritoneum by injections of antivirus prepared from dextrose broth cultures of colon bacilli and the cultures of streptococci and colon bacilli. Old, twelve to fifteen day cultures were filtered, reinoculated, and then again filtered after incubation for several days.

The experiments will not be cited in detail, because attempts to use these filtrates for intraperitoneal immunizing injections were not successful; they were too toxic. Even autoclaving at 18 pounds' pressure for half an hour did not entirely destroy this toxicity. Doses of 5 to 10 cc. did not have a protective effect, and 15 cc. often proved fatal. These negative results fail to supply an experimental basis for the apparently favorable clinical results of Kittinger.<sup>13</sup>

Whatever may be the eventual status of antivirus in the treatment of peritonitis, it seems to me that my failure to produce immunization with these exhaust filtrates, as contrasted with the definite protection conferred by a vaccine of bacterial cells in physiologic sodium chloride solution, argues against the explanation that the increased resistance is due merely to nonspecific irritation of the peritoneum, for these filtrates certainly were irritants. I believe that the immunizing value of the vaccines is a specific factor depending on the antigenic properties of the bacterial cells.

---

13. Kittinger, A.: Die Behandlung der eitrigen Peritonitis mit keimfreien Koli- und Mischkulturfiltraten (*Antivirus*), *Wien. klin. Wchnschr.* 40:997, 1927.

Further evidence for this belief was gained by an attempt to lessen the toxicity of the vaccine, and thus allow the administration of larger doses, by autolysis under ether, according to the method of Rosenow.<sup>14</sup> After autolysis for seventy-two hours, the toxicity was definitely lessened, but the immunizing effect was also lessened, whereas, from 1 to 2 cc. of fresh vaccine gave protection, and 10 or 15 cc. of autolyzed vaccine did not.

I have already mentioned the observation that two successive intraperitoneal injections, 1 and 2 cc. respectively, of vaccines of streptococci and colon bacilli give protection against subsequent fecal soiling, while only one injection does not, and I have pointed out that this indicates the development of a specific immune factor other than local hyperemia and leukocytosis.

I believe it safe to conclude, then, that the protection afforded by the intraperitoneal injection of vaccines of streptococci and colon bacilli is due to the development of a specific local peritoneal immunity against these organisms.

*Comparison of the Cultures of the Heart Blood of Rabbits After the Intraperitoneal Injection of Dog Feces.*—The basis for employing a vaccine of streptococci and colon bacilli for immunizing rabbits against dog feces was the frequent recovery of a symbiotic culture of these organisms from the heart blood of rabbits that died soon after the intraperitoneal injection of feces. It is interesting to compare the results of culture of the heart blood in all rabbits, immunized and unimmunized, which were injected with feces in various experiments.

I speak of this mixed culture as symbiotic because the streptococcus (perhaps more correctly gram-positive diplococcus, since chain formation was not marked) apparently was a partial oxygen tension organism. It grew in the deeper portion of tubes of dextrose broth, apparently depending on the colon bacillus, which often formed a surface pellicle, to establish the required lowering of oxygen tension. It was difficult to separate the two organisms, because the coccus would not grow alone. When it seemed to be in pure culture, subcultures would not grow. It would not grow on the surface of blood agar plates, but several cultures which were fished from the depth of the blood agar did not show a surrounding zone of hemolysis, but a slight greenish tinge. It belongs in the viridans group. I was unable to make satisfactory tests of the pathogenicity of the coccus alone, but 5 cc. of the symbiotic cultures, freshly isolated, injected intraperitoneally into a rabbit killed the rabbit over night. The same combination was then isolated from the heart blood of this rabbit.

---

14. Rosenow, E. C.: On the Production of Anaphylatoxic Substances by Autolysis of Bacteria and Their Relations to Endotoxins, *J. Infect. Dis.* **10**:113, 1912.

Several cultures of heart blood showed a mixture of organisms, sometimes including a large gram-positive bacillus, probably Welch's bacillus. Excluding these there were sixty other rabbits that had been injected with feces. Cultures of these showed: streptococci alone in three, streptococci and colon bacilli in twenty-one, colon bacilli in sixteen, and negative cultures in twenty.

Eight surviving rabbits, showing negative cultures when killed, had normal peritoneums and were otherwise normal because of high immunity. Cultures of heart blood were not made of all of the other surviving rabbits, as they were not killed. Excluding these eight, the remainder can be divided into three groups:

In the first group, the animals died on the first day. Little if any peritonitis was present. Streptococci were found in three; streptococci and colon bacilli in nineteen; colon bacilli in nine, and cultures of heart blood were negative in one.

In the second group, the animals died or were killed on the second to the fifth days. Definite peritonitis was present. Streptococci and colon bacilli were found in two; colon bacilli in six, and cultures of the heart blood were negative in five.

In the third group, the animals died or were killed after five days. A high degree of peritonitis was present. Colon bacilli were found in one, and cultures from the heart blood were negative in six.

In accordance with the conception outlined, peritonitis indicates a defensive reaction dependent on local immunity. The first group represents animals with little if any peritoneal immunity. Death, therefore, occurred early because of bacteremia, approximately 60 per cent of the animals showing streptococci and colon bacilli and 30 per cent colon bacilli alone. The second and third groups represent partially immune animals. If definite peritonitis developed (second group), the streptococcus was less frequently found in the blood (15 + per cent), and bacteremia from colon bacilli was relatively more common (45 per cent). The peritoneal defense apparently checked the streptococci, but was unable to restrain all of the relatively much more numerous colon bacilli. After a high degree of peritonitis was established (third group), the heart blood at necropsy was usually sterile. Death in cases of fully developed peritonitis, then, does not appear to be associated with bacteremia.

These data serve to emphasize the relative frequency of the presence of streptococci and colon bacilli in the blood when death occurs early after fecal soiling of the peritoneum. They also give further support to the conception that peritonitis is a defensive process dependent on immunity. It seems correct to divide animals into three groups, according to the degree of peritoneal immunity: (1) not immune, absence of

peritonitis, early bacteremia; (2) partially immune, grades of peritonitis indicating grades of immunity, bacteremia less common, and (3) entirely immune, neither bacteremia nor peritonitis, because of prompt complete control by the forces of immunity.

#### CONCLUSIONS

Peritonitis, induced by the reaction of the peritoneum to bacterial infection, is a defensive process. Its development depends on the presence of immunity. This immunity is probably locally increased resistance of the peritoneum rather than general humoral immunity. Such immunity can be built up by intraperitoneal vaccinations. Relatively low peritoneal immunity leads to peritonitis, while relatively high peritoneal immunity leads to recovery without peritonitis.

Streptococci and colon bacilli represent the most significant pathogenic element in feces. Intraperitoneal injections of a vaccine of colon bacilli alone afford a slight degree of protection against subsequent fecal soiling. Intraperitoneal injections of combined vaccine of streptococci and colon bacilli are strikingly effective. This protective effect is probably due to the development of specific local peritoneal immunity.

### URETER

*Surgical Technic.*—Bailey<sup>34</sup> reported a case of nephro-ureteral anastomosis. In an attempt to remove an impacted stone from the renal pelvis, the pelvis suddenly became detached from the kidney. The ureter could be seen lying limply attached to the kidney by a shred of tissue. The stone was then easily removed. The next consideration was to repair the injury. Nephrectomy was out of the question because of the uremic condition of the patient and because of a large calculus in the other kidney. There was little hope of obtaining functional anastomosis, but, because of the possibility that even a renal fistula would tide the patient over the crisis of the removal of the stone from the opposite kidney, the following procedure was adopted: the small transverse incision in the hilum of the kidney was extended toward the convex border. The torn edge of the pelvis was sutured, at first to the lower and then to the upper lips of this wound. The whole suture line was then reinforced by a superimposed muscle graft. The kidney was replaced and the lumbar incision closed with drainage. There was a fairly profuse discharge of urine from the lumbar wound for a week. Six weeks later, a large calculus was removed from the opposite (right) kidney. At the end of three months, cystoscopy showed the left ureter working well but not as actively as the right. One year later, the lumbar wound broke down and discharged urine. The patient was in good health and at work.

---

34. Bailey, Hamilton: Nephro-Ureteral Anastomosis, J. Urol. 20:103, 1928.

He was free from pain, but the left lumbar wound discharged about 4 cc. of pus every third or fourth day. The blood urea was normal.

Begg reported a case in which the operation was rendered necessary by an accident similar to that in Bailey's case. During nephrolithotomy, after the stone had been removed through the pelvis, some traction had to be exerted in order that the incision in the renal pelvis might be closed. It was at this stage that the ureter tore completely away from the pelvis at the line of a circular ulcer. Only a few ragged pieces of tissue remained around the renal hilum. A no. 6 French catheter, butt end down, was passed down the ureter. The eye of the catheter was passed into the major renal calix. The upper end of the ureter was split and, by means of stitches, was so fixed that the margins were approximated roughly to the frayed renal pelvis. A capsular flap was then turned down to cover and reinforce the suture line. To insure adequate drainage, the pelvis was opened from the cortex, and a drainage tube tied in. The catheter was subsequently removed from the bladder by an operating cystoscope.

These cases demonstrate that the kidney proper may be anastomosed to the ureter with at least a temporary functional result. It has yet to be proved whether this function can be permanently maintained.

[ED. NOTE.—Recent experiments on laboratory animals such as those reported by Kramer indicate the rapidity of ureteral regeneration and healing. Sometimes an incomplete anastomosis will prove effective, and the urine finds the normal outlet even under unfavorable circumstances. In one case of resection of the bladder for carcinoma, 2 cm. of the left ureter was removed and the remaining ureteral segment was tied. Four months later, cystoscopy revealed that the ureter was patent; it had connected with the bladder through the line of resection and was ejecting a moderate amount of urine. A ureteral catheter was inserted for a normal distance in the ureter.]

Mason<sup>35</sup> cited the case of a boy who lived comfortably for three years after transplantation of both ureters into the sigmoid and who died following an operation for acute intestinal obstruction due to a band associated with tuberculous mesenteric lymph nodes. Lateral anastomosis was performed. At the end of the operation there was a marked degree of collapse, but this was quickly overcome, and for a while everything seemed to be progressing favorably. After two days a change for the worse was manifested, and the condition retrogressed rapidly, death occurring on the fifth day. Necropsy showed that the rectum was distended and its muscle definitely hypertrophied. The mucosa below the level of the ureteral openings was the seat of mild catarrhal inflammation. The right ureteral orifice was patulous. The

---

35. Mason, G. A.: Transplantation of Ureters for Congenital Incontinence; Final Results, *Arch. Dis. Childhood* 3:109, 1928.

mucosa had prolapsed, giving it a button-like appearance, and it was the seat of inflammatory changes similar to those seen in the neighboring rectal mucosa. The left ureteral orifice was difficult to find; it was a mere slit through which a fine bristle had been passed, in contrast to the other patulous ureter. The right kidney was markedly shrunken. Section showed that it consisted chiefly of a dilated pelvis and calices. The condition was that of advanced pyonephrosis. The left kidney was of normal size. The cortex was swollen, and the vascular markings stood out prominently. The pelvis and calices were slightly dilated, the former merging imperceptibly with the ureter.

Despite the apparently advanced degree of renal infection found at necropsy, the child, until a few days previously, had not only appeared healthy but had led the ordinary life of a school child without any inconvenience.

*Regeneration.*—Kramer<sup>36</sup> commented on the need of methods of ureteral repair after certain types of injury to the ureters from trauma or infection, or the injuries incident to operation. He showed that all operations on the ureters from the standpoint of anastomosis fall into two groups, end-to-end and end-in-end. The author noted that McArthur described a method of ureteral repair which consisted of end-to-end anastomosis over a catheter. He noted also the tendency for epithelial lined ducts to regenerate over a splint.

To determine the rate of ureteral regeneration, the following operative procedure was carried out on dogs: An incision was made through the lumbar region; the kidney was delivered and the ureter located and dissected downward so that the middle third was exposed. In this portion was made a longitudinal incision, long enough to admit two no. 5 French ureteral catheters. One catheter was passed upward into the renal pelvis; another catheter was passed downward into the bladder, and the ends of both were brought out of the lumbar wound. At a point about 3.5 cm. below the longitudinal incision, the ureter was completely cut across, and the cut edges were brought together by one silk suture. The wound was closed by layers. In the first experiment, the catheters were removed after five days, a urinary fistula persisting for three weeks. This closed during the fourth week, and the animal was killed. Periureteral fibrosis was noted at the area of the fistula, and some constriction was found at the sites of the incisions. The mucosa at the site of the anastomosis was grossly unaltered. In the second experiment the upper catheter leading from the renal pelvis was removed on the fifth day, the other catheter being left in situ. A urinary fistula persisted until

---

36. Kramer, S. E.: Observations on the Rate of Ureteral Regeneration; Preliminary Report, Surg. Gynec. Obst. 46:216, 1928.

the dog was killed two weeks later. While periureteral fibrosis was more marked than in the first experiment, the point of anastomosis showed a fine annular scar practically without constriction. In the third experiment about 2 cm. of the ureter was excised and the ends were not brought together, one loose silk suture being used to prevent further retraction of the ureteral edges. Urine began to be expelled from the upper catheter at once. On the fourth day, both catheters were removed. A urinary fistula developed and persisted for three weeks, when the dog was killed. The affected ureter was found thickened throughout its course. Although the mucous surface of the area of regeneration was similar in appearance to the other portions of the ureter, the lumen at this site was constricted to about a third of the diameter of the portion below, and there was dilatation of the ureter above the site of the area of regeneration.

Kramer reported these preliminary experiments to show that the rate of ureteral regeneration is probably more rapid than is usually supposed. He expressed the belief that splinting with the catheter will bring about ureteral regeneration, even when there is lack of continuity after five days. The presence of the splint, rather than the escape of urine, is responsible for the degree of periureteral fibrosis.

Kramer also pointed out that some degree of stenosis occurs with any type of ureteral anastomosis. This is to be combated by early removal of the splint and early dilatation of the ureter by cystoscopy.

[ED. NOTE.—Much confusion exists as to the best type of ureteral anastomosis. In the intestinal, biliary or urinary tracts, however, the trend of the time is to get back to end-to-end union when possible. The use of a splint of the catheter type has advocates and opponents. The foregoing experiments are of interest, although the small number of protocols cannot be accepted as final evidence. There is need for study of the rate of ureteral regeneration and the effect of leaving the catheter in situ over a period of time. The shunting of the urinary stream temporarily above the site of anastomosis seems an excellent idea and may be a factor in the early regeneration of the urinary tubule. The method seems worthy of trial clinically.]

*Obstruction.*—Smith and Ockerblad<sup>37</sup> conducted experiments by partially obstructing the ureters of fourteen dogs. Their observations were striking in several ways. There was rapid and permanent dilatation in the ureter and renal pelvis, in spite of indisputable evidence that urine was passing through the obstruction. The formation of kinks was noted. Seemingly normal blood vessels were also noted which led to or

37. Smith, C. K., and Ockerblad, N. F.: Partial Obstruction of the Ureter; Experimental Study, *J. Urol.* 19:347, 1928.

from a kidney and became "aberrant vessels" in a short time because of marked change, not only in the size of the kidney and its pelvis, but in its position. The ureteral tortuosities and kinks obviously did not result from the descent of a greatly enlarged and congested kidney, as has been claimed by clinical observers, since in dogs gravity does not have a great influence, the pull being rather forward. These authors found that the upper pole of the kidney on the obstructed side was actually several centimeters higher than that on the unobstructed side. There was also a definite lengthening of the ureter of several centimeters, together with a tendency for the tortuous and kinked ureter to place itself nearer the median line and to rotate on its long axis.

They found that partial obstruction of the ureter caused an entirely different series of abnormal changes from those resulting from complete obstruction of the tube. They were especially interested in the ureter, but noted that injury to the ureter does not occur experimentally apart from serious changes in the renal pelvis and parenchyma. The injury to the ureter is in direct relation to the point of obstruction; the nearer it is to the bladder, the greater is the ureteral tortuosity and redundancy.

The renal pelvis in a partially obstructed ureter may obstruct the vena cava, and this enlarging pelvis may also so stretch blood vessels which in the beginning were normal that they may become the so-called aberrant vessels. In this respect dilatation of the renal pelvis or ureter may produce an aberrant vessel, and an aberrant vessel may produce obstruction to the ureter.

Fibrous bands which form may become permanent adhesions and may bind the ureter in its new position, even after the obstruction has been released.

Ureteral kinks, which have been reckoned by some clinicians to be the causative factors of symptoms attributed to ureteral obstruction, are apparently only a by-product of ureteral obstruction. In this connection, the authors conclude from this evidence, together with clinical observation, that the obstruction which produces the kink is likewise a real factor in producing the clinical symptoms.

Pápin<sup>38</sup> reported a case in which hysterectomy had been performed. Two days after the operation urine had not been passed, and the bladder was empty. Cystoscopic examination revealed ureteral obstruction several centimeters from both ureteral orifices. At a second operation, both ureters were found to have been ligated at the level of the uterine artery. The ligature was removed and ureteral catheters inserted into the ureters above the point of ligation. The lower end of the catheter

---

38. Papin, Marc: *Ligature opératoire des deux uretères; Désobstruction*, Bull. et mém. Soc. nat. d. chir. 54:1026, 1928.

was passed down into the bladder. These catheters were left in place six days, and the convalescence was uneventful. Legueu, in discussing this case, stated that he did not believe it necessary in such instances to insert the permanent ureteral catheters.

*Stricture.*—Legueu and Fey<sup>39</sup> stated that ureteral strictures are often multiple and almost always bilateral. They usually develop in the ureteral wall as a secondary focus of infection. These patients are found in the clientele of general surgeons and have frequently been operated on uselessly for appendicitis or disease of the biliary tract.

Pain, which occurs in the region of the kidney, varies from simple pressure to violent nephritic colic. About 70 per cent of patients have frequency of urination, burning or incontinence. The kidneys are painful on palpation, and in a number of cases examination of the urine shows manifestations of pyelitis. Ninety per cent of 400 patients with pyelitis treated by Hunner had a ureteral stricture. A large number of patients with hydronephrosis also had ureteral strictures. The treatment consisted in dilatation of the ureter by ureteral sounds.

The authors stated that at the clinic of Necker, where they practice, inflammatory stricture of the ureter is unknown. They have observed traumatic strictures, postoperative strictures and strictures following a ureterovaginal fistula, but never primary inflammatory ureteral strictures.

Vermooten<sup>40</sup> and his associates produced ureteral strictures in female dogs. In one experiment, this was done by injuring the peritoneum over the ureter. In other instances, injections of suspensions of colon bacilli were made into the wall of the ureter. Each dog was examined by cystoscopy and pyclograms before the experiment, and the urinary system was found to be normal.

These few experiments showed that strictures of the ureter can be produced artificially in dogs and that, although it takes a comparatively long time to produce gross changes in the renal pelvis and the ureters proximal to the strictured area, these occur uniformly and are apparently progressive in nature. The chief gross changes which occur are dilatation of the renal pelvis and dilatation and tortuosity of the ureter; microscopically, there is fibrosis and small round-cell infiltration at the site of the stricture.

The dilatation of the kidney is an important observation, and it might explain an occasional case of the right-sided pain which sometimes occurs after appendectomy, especially if an actually inflamed appendix

39. Legueu, F., and Fey, B.: *Les rétrécissements de l'uretère*, J. d'urolog. **25**:417, 1928.

40. Vermooten, V.: van Wart, W. H., and Kearney, E. P. J.: *Ureteral Stricture: An Experimental Study; Preliminary Report*, J. Urol. **19**:341, 1928.

lay in the proximity of the ureter. It might also make one suspect the possibility of ureteral stricture in patients who have had pelvic operations during which the ureter was exposed or the peritoneum over it torn.

Hunner<sup>41</sup> stated that most patients with calculus in the upper part of the urinary tract are subject to some form of urinary stasis. The most frequent cause of this stasis is ureteral stricture. He reported ultimate results in a series of seventy-eight cases, thirty-three of renal calculus and forty-five of ureteral calculus.

Hunner concluded that some of the advantages of ureteral dilatation are that: (1) thorough dilatation leads to the spontaneous passage of a large percentage of ureteral stones; (2) the total renal function is increased and the patient's general health improved preparatory to operation; (3) the establishment of drainage often renders certain cases favorable operative risks which otherwise would not be considered as such; (4) many patients who cannot be operated on because of advanced age, obesity or cardiac or pulmonary lesions are made more comfortable and life is prolonged through the establishment of better ureteral drainage; (5) prolonged postoperative sinus drainage is avoided, and a much higher percentage of patients leave the hospital without urinary infection, and (6) there is a decreased tendency to the recurrence of calculus in the kidney operated on, as well as a lessened tendency to the formation of calculus in the opposite kidney.

*Spasmodic Contracture.*—Grégoire and Wolf fromm<sup>42</sup> stated that although reflex anuria is a well-known occurrence, its cause is only explained on theoretical grounds. One group of observers assumes that spasm of the ureter is the momentary cause, and others believe that a lesion of the kidney is present.

The authors cited a case in which a ureteral spasm resulted in long-standing anuria. The patient, a woman, aged 29, at the time of menstruation had severe pain in the loin which radiated toward the bladder and the thigh. Examination revealed uterine fibromyoma, which was removed under local anesthesia. For two days she did not pass urine. On catheterization, the bladder was empty. Both ureters could be catheterized only for a distance of 6 cm. Later, both catheters were pushed up to the pelves which were also found to be empty. Urine was not secreted in spite of pelvic lavage and the intravenous injection of dextrose solution. The operative wound was reopened, and inspection

of the ureters did not reveal a cause for the anuria. Catheterization again revealed the bladder to be empty. The bladder was then filled under pressure, and a retention catheter was left in place. The following day, 3 liters of urine was secreted. Three days later the patient had another attack of anuria, and the bladder was again distended. After that, the patient was well.

For an explanation of this phenomenon, Grégoire and Wolfrohm cited the experiments of Legueu in which he proved that by mechanical stimulation of the lower ureter, antiperistalsis results and extends up to the renal calices. He believed that such movements in their extreme effect may lead to a spasm such as has been similarly observed in the esophagus, stomach or intestinal tract.

#### PROSTATE

*Hypertrophy.*—Hunt<sup>43</sup> reviewed a series of 1,000 consecutive cases of benign prostatic obstruction in which suprapubic prostatectomy was done. He emphasized the fact that, for the successful treatment of this condition, it should be regarded from a general medical point of view.

True adenomatous hypertrophy comprises about 85 per cent of benign obstructing prostatic lesions, the remainder being of the inflammatory or prostatic type. Although the inflammatory type is encountered often at an earlier age than adenomatous hypertrophy, there is little difference in the age incidence in cases of obstruction and retention from the two types of glands. Prostatic fulness and enlargement are found on careful digital examination in more than 50 per cent of men, aged 50; however, the incidence of obstruction and the symptoms of benign prostatic disease are rare at this age or under this age. The average age in Hunt's series was 64 years. Although a small gland may produce intra-urethral obstruction and complete retention, a huge intravesical gland may provide adequate urethral passage without urinary retention. The moderate sized gland is the usual enlargement productive of retention.

Cystoscopic examination is not necessary except in cases in which the digital examination does not afford evidence which unreservedly explains the urinary symptoms. Retention and residual urine, when definitely attributed to the prostate, form the true indications for prostatectomy. Urinary retention requiring catheterization existed in more than 50 per cent of the cases in the series.

In preoperative treatment, patients with prostatic obstruction are as a rule poor subjects for immediate operation. Hunt noted that the mortality rate in cases in which the patient seems to be in good physical

---

43. Hunt, V. C.: Benign Prostatic Hypertrophy: a Review of One Thousand Cases, Surg. Gynec. Obst. 46:769, 1928.

condition and is operated on without preliminary treatment approaches that of patients in a poorer condition who have had proper preliminary treatment. For the last three years at the Mayo Clinic, preliminary treatment for a minimum of ten days has been carried out in all cases requiring prostatectomy. Drainage of the bladder is of prime importance; it is established by means of an indwelling permanent urethral catheter and is continued until the cardiovascular renal reserve has been restored to the point of relative safety. Permanent catheter drainage is the method of choice because it facilitates the one-stage visualized operation. Suprapubic drainage is necessary under the conditions of associated vesical lesions, such as stones and diverticula, and in those cases of marked renal insufficiency requiring a long period of drainage preliminary to prostatectomy. Intolerance of the urethral catheter occurred in 6 per cent of Hunt's cases. Suprapubic drainage means a second-stage blind enucleation of the prostate with results that are not so satisfactory as those obtained with the one-stage visualized operation. Suprapubic drainage was necessary in 28.8 per cent of cases. Prostatectomy should not be considered in any case in less than three weeks from the cystostomy. Approximately half of the patients were operated on within an interval of a month.

The general condition of the patient is the important guide to the time at which the prostatectomy is to be considered, the tests of renal function serving to indicate the danger of operation rather than its safety. A consistently low phenolsulphonphthalein return or a persistently high blood urea estimation indicates a narrow margin of reserve, and only under most unusual conditions may prostatectomy be undertaken if the renal function is less than 20 per cent or if the stabilization of the blood urea is much more than 50 mg. for each hundred cubic centimeters.

The one-stage operation was performed in 72 per cent of Hunt's series. Regional anesthesia is the one of choice and has displaced general anesthesia in this field of surgery because it minimizes postoperative renal depression and pulmonary complications from inhalation. Accurate hemostasis is most important, as continued bleeding exerts a profound influence on the subsequent advent of sepsis and pyelonephritis. The Pilcher bag, which was used in 850 cases of this series, proved a most effective method of hemostasis when utilized with hemostatic control by suture at the vesical neck.

The mortality from prostatectomy will vary, and an incredibly low mortality may be obtained for a considerable time and for a considerable number of consecutive cases through careful selection of patients, the benefits of operation being denied to those with a narrow margin of cardiovascular reserve. With the acceptance of only such conditions as

cardiac decompensation, coronary sclerosis with evidence of marked myocardial injury and advanced malignant hypertension as contraindications to prostatectomy, operation was performed in 140 consecutive cases after adequate preoperative treatment with one death. Four deaths occurred, however, in the next fifty-four cases, making a mortality rate of 2.5 per cent in 194 cases in which operation was performed during that year.

On the other hand, previous to the adoption of the principle of preoperative drainage, 36 per cent of the patients were operated on without preoperative preparation with a mortality rate of 6.6 per cent. The mortality rate in the 1,000 cases for a period of eight years was 5.4 per cent. General sepsis, uremia and pyelonephritis were the most important causes of death. Pulmonary embolism occurred in eight cases; coronary sclerosis was the cause of death in two, pneumonia in three, and bleeding duodenal ulcer in one case. The results of operation as determined from the patients' statements regarding relief from prostatic symptoms were good, 85 per cent stating that they were completely or almost completely relieved.

[ED. NOTE.—The study of this series of cases is of interest in that it points out the value to be obtained by careful coordination of the various phases of treatment in prostatic disease. Hunt, probably as much as any surgeon, has simplified the technic of suprapubic prostatectomy to such an extent as to make the execution of the operation and the end-results obtained equally as satisfactory as those obtained by the perineal operation in the hands of its most skilful advocates.]

The importance of preoperative treatment even for the patient who appears to present a good risk according to all the tests of clinical and laboratory type is certainly demonstrated in this review and is in itself a remarkable contribution to the knowledge of prostatic disease.]

The death rate in 126 cases of suprapubic prostatectomy reported by Edwards<sup>44</sup> was 8.7 per cent. Four of these patients were operated on in two stages; one patient died. The remaining 122 cases were done in one stage. The mortality in this group was 8.2 per cent. There was only one death due to hemorrhage (0.8 per cent). The mortality from operative shock was less than 0.8 per cent. In two cases of death due to pyelonephritis, the renal calices and pelves were dilated. In three of four cases in which uremia was the cause of death, sepsis played a part. Sepsis and uremia together accounted for 60 per cent of the deaths following the one-stage operation. Edwards believed that this relatively high mortality may be eliminated by earlier operation.

## BLADDER

*Stone*.—Krasnobajeff<sup>45</sup> stated that the mortality following lithotripsy in children is low. The stones in the bladder of children are of a composition which permits crushing. In three of 102 cases, the stones were composed of oxalates. In 91 per cent of the cases the stones contained urates and in 7 per cent phosphates. In 60 per cent of 168 cases in which the size of the stone was measured, it was 2 cm. in diameter. In six cases the stone was 4 cm. in diameter and in one case, 5 cm. In 50 per cent of the cases the stone was so small that it was necessary to pass the lithotriptor only once, and in only 8 per cent was it necessary to insert it four or more times. The average period of time occupied was twenty-four minutes; the minimal time was from three to five minutes, and the maximal, ninety-two minutes.

A group of various reports indicates the low mortality following this operation. Alexandroff reported 574 cases with nine deaths. Krasnobajeff reported 189 cases with two deaths, and in another series of 117, operation was performed prior to 1901 with two deaths. In all, lithotripsy was performed 880 times with thirteen deaths, an operative mortality of 1.5 per cent. It is interesting to compare these figures with those reported by Guyon, who reported 4,000 cases with a mortality of 2 per cent. Lithotripsy gives a shorter period of convalescence than does the open operation, and the author stated that recurrence is not more common than with the open method.

Rocher and Blanc<sup>46</sup> reported a case of vesicorenal lithiasis in a child aged 3 years, whose mother had been operated on at the age of 3 years for stone in the bladder and two of whose sisters had likewise had stones in the bladder. In this case the symptoms were typical, and cystoscopy confirmed the diagnosis. Roentgen examination showed four calculi in the bladder and, in addition, a calculus of the same shape, size and opacity at the level of the pelvis of the left kidney. The four vesical calculi were removed by cystotomy. Two weeks later the right lumbar region became painful and rigid, and the patient's condition was grave. The kidney was exposed, and the stone was removed from the neck of the ureter. Death took place two weeks later from pyelonephritis. In lithiasis in infants the frequency of heredity in the formation of stone, the frequent absence of macroscopic hematuria and the necessity of taking roentgenograms of the entire urinary tract in every case should be borne in mind.

46. Rocher, H. L., and Blanc, H.: Case of Urinary Lithiasis in an Infant, *Gaz. hebdomadaire de médecine et de chirurgie* 49:203, 1928.

Liebl<sup>47</sup> reported the case of a woman, aged 54, who was operated on twice within a period of five years for vesical and uterine calculi. One year after the first operation, she passed a small vesical stone. At the second operation, the bladder was completely filled by one large stone. The uterine stones were wedged tightly in the cervix. This is said to be the only case of its kind on record.

*Nerve Control.*—McClintic<sup>48</sup> stated that there are two emptying mechanisms for the bladder, the so-called visceral or involuntary and the voluntary or somatic. The latter has been added to enable the organism to adapt itself somewhat to its environment when it is essential for these organs to empty.

The bladder consists of three layers, a mucous membrane on the inside, a middle muscular layer and an outer fibrous layer. The sensory nerves terminate in all of these layers. On the outer layer are small nerve ganglions and plexuses. The sensory nerves carry all afferent impulses to the spinal cord. The inhibitory nerve fibers terminate in the muscles. The nerves which transmit the motor impulses and which cause contraction of the wall of the bladder relay in the ganglions on the bladder, and from the cells of the ganglions fibers arise which run to the muscles of the wall of the bladder.

McClintic concluded that transverse lesions of the cord below the red nucleus result in the establishment of an automatic bladder. The voluntary emptying mechanism of the bladder is controlled from the cerebrum and the involuntary mechanism from the spinal cord.

*Diverticula.*—Stirling and Rollings<sup>49</sup> stated that the most common site for diverticula is at the upper and lateral margin of the trigone. If drainage is adequate and infection is not present, the diverticulum usually is not of clinical significance.

In making the diagnosis the authors stated that a series of three or more plates should be used in making cystograms, which should consist of an anteroposterior view, a lateral view to show the retroversical type, and one after the bladder is emptied to show whether retention in the sac occurs. An opaque catheter coiled up in the diverticulum and a lead catheter in the ureter on the affected side are valuable aids in the diagnosis of this condition.

Six of the cases reported by Stirling and Rollings presented unusual features: the first, a relatively rare dumb-bell type of stone in the bladder

49. Stirling, Calhoun; and Rollings, H. W., Jr.: Diverticula of the Bladder; Remarks Founded upon a Study of Twelve Cases, Ann. Surg. 87:742, 1928.

and diverticulum; the second, a diverticulum of the bladder associated with a diverticulum of the ureter; the third, an enormous diverticulum with eight associated diverticula which held 1 liter; the fourth, a large diverticulum of the bladder of a female without obstruction; the fifth, a diverticulum of the bladder with both ureteral orifices opening into it, associated with a high degree of hydro-ureter and hydronephrosis; the sixth, a large vesical calculus associated with two diverticula of the bladder. In seven of the twelve reported cases, operation was successful. Three cases were inoperable as a result of cardiorenal disease; in the remaining two, palliative treatment was given.

Four of the reported cases occurred in females. This is unusual, as the majority of the reported cases have occurred in males.

*Deformity.*—Laskownicki<sup>50</sup> reported a case of hypertrophy of the interureteral ridge which was apparently congenital in origin. This hypertrophy was the cause of complete obstruction to urination. This difficulty in urinating increased slowly but steadily every day until at last the capacity of the bladder reached the enormous quantity of 2 liters. The patient died following cystostomy.

Postmortem examination revealed hypertrophy of the interureteral ridge. The bladder was markedly thickened, and several diverticula as well as bilateral hydronephrosis and cysto-ureteropyelonephritis were present. The patient probably had never been able to empty the bladder. The capacity of the bladder increased more and more. At the same time, on account of frequent contraction of the muscles of the trigone, all efforts to empty the bladder of residual urine being fruitless, the trigonal muscle underwent continuous hypertrophy which, in its turn, caused hypertrophy of the interureteral ridge.

*Complication of Cystotomy.*—Beer<sup>51</sup> stated that following suprapubic operation on the bladder he has repeatedly observed a curious and painful complication of periostitis involving the bones of the pelvis, usually starting in the bodies of the pubic bones. This condition is apparently a mild infection secondary to operation on the bladder. It usually occurs only when the bladder has been opened. Patients complained of pain when they tried to sit up or when they coughed, due to the fact that the rectus muscles pulled against the inflamed attachment at the symphysis. Some of the cases are mild, and the trouble is apparently localized in the attachment of the rectus muscles; but in the majority the process extends along the descending ramus of the pubis, so that the patients have pain and tenderness along the attachment of the

adductor muscles which interfere with walking and with the movement of the two thighs. The disturbance may last for several months. Physical signs are usually slight. A roentgenogram of the pubis may show fraying of the periosteum, although it is usually far from conclusive in the early stages.

*Perivesical Suppuration.*—Culver and Baker <sup>52</sup> stated that perivesical suppuration, although not common, is one of the end-results of perivesical inflammation, regardless of the etiology of this inflammation. The primary cause of the suppuration may be of such a nature as to prevent cure, but the mortality from the suppuration itself should not be high if the condition is recognized and proper drainage instituted. The morbidity is usually due to the general effect of long-continued sepsis.

The authors suggested that preliminary cystotomy be made in all cases in which perineal section is contemplated in chronic perineal sepsis, such as is seen in multiple perineal fistula. This makes a safer field for perineal section later.

*Fistulas.*—Bengolea <sup>53</sup> reported thirty cases of vesicovaginal fistula. In three, operation was performed by the abdominal route; the results were not good. In twenty-seven, operation was performed by the vaginal route; 64.4 per cent of the patients were cured. Twenty-four of the fistulas resulted from childbirth; three followed operation and one followed radium. Twelve of the fistulas extended from the bladder to the vagina, four involved the cervix and the vagina, one was vesico-ureterovaginal, and one was ureterovaginal.

Legueu reported somewhat similar statistics. He performed the transabdominal operation in eight cases, with five cures and three failures. In fifty-five cases in which operation was performed by the vaginal route, there were thirty cures (54 per cent). Legueu believed that the following procedure should be carried out: for fistulas situated low in the bladder, the vaginal route is superior; this procedure is easy, simple and efficacious and may be repeated if necessary; for fistulas situated high in the bladder, the suprapubic route is superior, and for postoperative fistulas the abdominal route, although more dangerous, should be used on account of the more successful results.

Garmsen <sup>54</sup> reported three cases of incontinence due to vesicovaginal fistulas. Operation was performed as follows: The fallopian tubes

were first resected, and the lower part of the small intestine was freed without destroying its mesenteric connection. An intestinal ring, 12 to 15 cm. in diameter, was formed by end-to-end anastomosis. The rectum was freed from surrounding attachments, and the mucous membrane was separated from the margin of the skin. The intestinal ring was connected to the external anal sphincter, which had been resected from the anterior wall of the rectum. In this way there were two openings through this sphincter, the newly made urethra and the rectum. After three days, the intestine was opened, given daily lavage and slowly dilated. After three months, the ureters were transplanted from the bladder to the intestine.

In the third case the entire procedure was performed in one stage, and at the same time the anal opening was placed about 3 cm. from the urethral opening. In all cases there was entire continence after the operation. One patient died two months after operation from pyelonephritis. The question to be solved is how to make the part of the intestine used for the bladder bacteria-free and thereby obviate infection of the kidney.

*Urinary Retention.*—In cases of postoperative retention of urine persisting for more than twelve hours, Fernand<sup>55</sup> recommended that 10 cc. of a solution of glycerite of boroglycerin (1 part to 5 parts of water) be injected into the full bladder. If the glycerite boroglycerin content is less than 20 per cent, it does not have any effect, and if it is greater, it tends to irritate the bladder.

*Tetany.*—Rohmer and Géry<sup>56</sup> reported a case of long-standing tetany in a young boy, who had trouble in emptying the bladder. There were tumor-like protrusions at both sides of the upper half of the bladder. Because the sphincter spasm which was present disappeared following antitetanic treatment and catheterization, the authors concluded that the case was one of tetany of the bladder.

#### SEMINAL VESICLES

*Diagnosis.*—Kartal<sup>57</sup> stated that in every case of spermatocystitis, the possibility of injury to the kidney of the affected side should be considered. If such injury exists, conservative treatment should first be tried to see whether improvement in the local process brings about improvement in renal function. If conservative treatment fails, seminal

55. Fernand, E.: Treatment of Postoperative Retention of Urine, *Rev. méd. de la Suisse Rom.* 48:212, 1928.

57. Kartal, S.: Ueber falsche Nierenkoliken, *München. med. Wchnschr.* 75:601, 1928.

vesiculectomy is the treatment of choice. Five cases were reported. In three the colicky pains had led to the diagnosis of appendicitis. In three, also, the renal function was disturbed. Sympathetic involvement of the ureter depends on the shape of the individual seminal vesicle rather than on its size. Involvement of the wall of the bladder depends on the site of the severest inflammatory process in the seminal vesicle, whether near or at a distance from the ampulla.

*Surgical Technic.*—Morrissey<sup>58</sup> reviewed the various methods of dealing with infections of the seminal vesicles and prostate which have been advocated during the last few years. Belfield's injection of the vas, injection through the ejaculatory ducts, and Stellwagen's injection of aqueous isotonic solution of iodine are mentioned. Emphasis has been placed on the prostate as a focus of infection, as shown by the work of von Lackum; he has shown that frequently nonspecific prostatitis and seminal vesiculitis of streptococcic type may be a factor in systemic or focal disease. The connection between perirectal and ischiorectal abscess and chronic infection in the seminal vesicles is significant and frequently is overlooked. Acute prostatic abscess may be a sequel of this focal condition.

Morrissey limited the selection of cases for operation to acute suppurative types and the rheumatic cases. The most favorable type of case for operation is that in which an acutely inflamed prostate and distended, painful vesicles develop, without unusual cause, during the course of treatment for ordinary gonorrhea. The development of these local changes, together with systemic manifestations, such as acute pain in the joints or high temperature, pain and general sepsis, is an indication for immediate drainage after a period of preliminary treatment for seventy-two hours. Rectal irrigations should be tried for three days and then continued if the condition improves. In general, operation is recommended in the acute cases provided other methods have been tried and are unavailing. It is wise to wait until the urethral discharge reappears, as its cessation may account for the joint manifestations. However, if in the presence of profuse or moderate discharge the prostate remains swollen and tender and the symptoms of involvement of the joints are severe, drainage should be instituted.

In a period of six years, Morrissey has performed operation in sixty-four cases of acute prostatitis and seminal vesiculitis. In addition, fourteen cases of chronic infections of the seminal vesicles have been treated by epididymectomy. Twelve cases of extensive peripelvic prostatic suppuration have been treated by operation, perirectal and superior pelvirectal abscesses having developed. Disappearance of pain and swelling,

---

58. Morrissey, J. H.: *Surgical Drainage of the Seminal Vesicles and Prostate; Its Indications, Technique and Results*, Surg. Gynec. Obst. 46:341, 1928.

subsidence of the fever, and decrease in the size of the prostate and perivesicular swelling have occurred immediately after operation. Prostatic or urethral symptoms did not recur. Fistula did not develop in any of the cases. Following operation on patients with disorders of the joints, pain subsided, swelling disappeared, and function returned in 80 per cent.

Attention is called to the existence of infection of the seminal vesicles in certain cases of enlargement of the prostate. The persistence of infection after prostatectomy may account for the delayed convalescence in these cases. Thompson-Walker advocated vesiculectomy at the time of prostatectomy, if infection is known to be present. In cases of chronic infection contributing to other symptoms, such as infection of the joint and referred or distant pain, operation should be the last resort. Sound judgment should be exercised in the care of these patients.

Persistent vesical infections may accompany or follow earlier epididymitis. In such cases the removal of the affected epididymis may be beneficial and is likely to cure both the vesical and the prostatic infection. Concerning the pathologic changes, it would seem that the essential factor in these conditions is the extension of infection along the ejaculatory ducts and into the perivesicular and periprostatic tissues. Resolution undoubtedly occurs in more than 96 per cent of the cases of perivesiculitis and periprostatitis, as is evidenced by the infrequency with which such cases come to operation.

Operative procedures are described as: (1) suprapubic, (2) inguinal, (3) transvesical, (4) perineal and (5) ischiorectal. Morrissey expressed the belief that suppurating complications of venereal infections are more and more being considered from the surgical standpoint. He considered the perineal operation as the method of choice.

Operation does not guard against recurrences in cases of rheumatism, and sterility and functional disturbances are to be reckoned with. Sterility is probably coincidental with the operation and is not caused by it. The periprostatic infection with infiltration of the ejaculatory ducts is largely contributory to the vesicular infection, and free and adequate drainage must be provided by liberal prostatic incisions. In cases in which venereal etiology is remote or recent, operation may be performed without undue risk and the mortality is nil.

Technically, Morrissey advocated the "exaggerated lithotomy" position of Young. The sound is inserted into the urethra and held in position. The incision runs from a point superficial to the ischial tuberosities and is carried in a curved line, the center of which should correspond to the point at which the urethra leaves the bulb to enter the prostate. The lateral fossae are dissected free by blunt dissection, the central tendon is carefully divided, and the apex of the prostate

comes into view. A vesical tractor is then introduced, the sound being removed. The prostate is elevated into view, and the fibers of the recto-urethralis muscle are dissected close to the capsule of the prostate. After dissection of the fibers of the recto-urethralis muscle, the existence of several planes of fascia constituting the capsule of Denonvilliers is recognized. Careful dissection is made upward along a plane extending posterior to the anterior wall of the retrovesical space. A second layer is then dissected back to the same point. Two fingers are then introduced, and the vesicles are felt stretched out to either side of the bladder. Enucleation from this position is made, a gauze sponge on a holder being recommended to aid in the enucleation. If the vas is ruptured, it is tied off. Vesiculotomy or vesiculectomy is then done. Incision of the prostatic capsule is recommended if there is much inflammation at this site. Two gauze wicks are inserted into the retrovesical space, the vesicles replaced, and two bits of rubber tubing inserted with the drains. The tractor is removed, the free edges of the levator muscles sutured together with a double suture of chromic catgut, and the skin is closed with interrupted sutures. The gauze is removed on the second day, and the rubber tubes are held in place. These are kept in position for five or six days and the cavity irrigated twice daily during this time. Patients are allowed to get up on the eighth or ninth day, and the sutures are removed as quickly as possible. The edges of the wound heal firmly by the third or fourth day and the center of the incision is kept open for drainage.

Hunt<sup>59</sup> described a method of posterior excision of the seminal vesicles. The patient is placed in a position similar to that used for the Kraske operation. A posterior median line incision over the sacrum is made and the tip of the coccyx cut off. Hunt derived his idea for this operation in noting the accessibility of the seminal vesicles through the posterior incision for resection of the rectum. In his operation for excision of the seminal vesicles, he avoids displacement of the anus and injury to the anal sphincters. Sacral anesthesia is preferred. The incision extends from about 2.5 cm. above the anus to just above the sacrococcygeal articulation. The incision is carried down to the levator ani. Mobilization of the rectum and the lower portion of the sigmoid and their lateral retraction expose the vesicles after division of the rectovesical fascia. After removal of one vesicle, the rectum is retracted to one side, thus exposing the remaining vesicle.

In none of the cases in which Hunt operated has a sinus resulted, and in all instances healing occurred without disturbance of the function of the levators or of the anal sphincters.

---

59. Hunt, V. C.: Posterior Excision of the Seminal Vesicles, *Ann. Surg.* 87: 257, 1928.

[ED. NOTE.—Morrissey has been one of those to advocate the perineal route in the treatment for seminal infections of the vesicle and prostate and has adduced much good evidence to support the rationale of the procedure. The perineal route in itself offers to many surgeons difficulties which seem to be a technical hindrance. Those who are adept at the operation of perineal prostatectomy would find little difficulty with the procedure, and a better understanding of the anatomy of the perineum with a little more care as to dissection should put the technique in the hands of the more conservative surgeon.]

Hunt's procedure seems even more simple and offers a new field for clinical endeavor in the approach to these deeply buried structures. He emphasized the superiority of surgical methods which allow the operator to work under direct vision. Although the dissection of the rectum and the excision of the coccyx expose a considerable amount of fresh tissue, the adequacy of exposure and the opportunity for accurate work under vision, together with good drainage, overcome this objection. The technique will undoubtedly be useful in certain cases.]

#### TESTICLE

*Tumors.*—Muto<sup>60</sup> reported on eight testicular tumors which he examined microscopically. One case was found to be a polymorphocellular sarcoma which had invaded the capsule and epididymis; invasion of the blood vessels was also noted.

Hemangioma was found in a boy, aged 2 years. It was in the mediastinum of the testicle and appeared to be on an embryonic basis.

Three of four cases of the so-called large-celled malignant testicular tumors were found to be pure carcinomas. In the fourth case, angiomatous areas, glandular tubules and cylindric cells were noted, as well as a sarcomatous stroma in the primary tumor. Cysts with cornified layers of squamous epithelium were also found in the lymphatic metastasis. Muto concluded from his observations that the large cell malignant testicular tumors should be included in the carcinomatous group. The large cell tumors are malignant and metastasize early, especially to the retroperitoneal lymph nodes. Trauma appears to play a part in their origin or further development. In four cases there was a history of trauma.

One case was that of an epithelial tumor in a child's scrotum and was similar in appearance to the large-celled carcinoma. The growth probably developed from an embryonic mixed tumor.

Another case appeared to be a typical embryoma in the form of a dermoid cyst. Chorio-epithelioma developed from fetal ectoderm.

### "LOBAR PNEUMONIA CONSIDERED AS PNEUMOCOCCIC LOBAR ATELECTASIS OF THE LUNG"

*To the Editors:*—I have read with a great deal of interest the article on lobar pneumonia by Coryllos and Birnbaum published in the ARCHIVES OF SURGERY of January, 1929, page 190. So radical a theory should not pass without consideration and comment. The authors have based their theory that bronchial obstruction is the important factor in the pathogenesis of lobar pneumonia on certain similarities between this condition and lobar atelectasis. I do not think that they have explained successfully the many differences between the two entities. I should like to call attention to one which, I believe, renders the theory untenable.

In atelectasis caused by obstruction of a bronchus supplying a lobe, the physical signs are flatness, absent breath sounds and decreased tactile and vocal fremitus. It has generally been believed that these signs persisted as long as the bronchus remained obstructed. In pneumonia the initial decrease in breath sounds soon gives way to dulness, pronounced bronchial breathing and increased tactile and vocal fremitus. The authors have explained this difference on the basis that in pneumonia the initial decrease in breath sounds is coincident with the onset of atelectasis, which, because of the greater proportion of alveoli at the periphery, is most marked in this portion of the lung. As soon as the interstitial inflammation, spreading from the hilum, and the atelectasis, spreading from the periphery have rendered the lobe completely atelectatic and consolidated, the sounds from the trachea and the patent hilar bronchi are transmitted through this uniformly dense tissue to the surface of the thorax. From this time on the signs become those of fully developed pneumonia, bronchial breathing and increased tactile and vocal fremitus. That this change of signs does not occur in the ordinary case of atelectasis they explain on the basis that usually atelectasis clears up before the collapse has extended to the hilum. They state that in prolonged cases of simple atelectasis true bronchial breathing does occur.

It seems to me that this is a vital point in their theory, and that the conception is tenable only if it can be shown that the physical signs of pneumonia are compatible with complete occlusion of the bronchus supplying a lobe. This necessitates as radical a change in the understanding of thoracic acoustics as does the theory in the ideas of the pathogenesis of pneumonia. Since the time of Laennec, it has been accepted that bronchial breathing and increased tactile and vocal fremitus are encountered only when there is solidification of the parenchyma and patency of the bronchi. That occlusion of the bronchus produces the signs of atelectasis has been held equally fundamental.

I have seen a large number of instances of bronchial obstruction and in all of them have found the physical signs of atelectasis, never those of pneumonia. This has been regardless of the duration of the obstruction. A case which I have under observation at the present time affords an excellent illustration of the point in question. The patient had a cicatricial stenosis of the bronchus supplying the lower lobe of the right lung, with atelectasis and bronchiectasis distal to the obstruction. The physical signs were those of atelectasis and remained so for several months until the stricture was dilated bronchoscopically by Dr. Chevalier Jackson. Following this the parenchymal collapse persisted in spite of the opening of the bronchus, and the signs changed to those characteristic

of pneumonia and other consolidations. I have also seen instances of virulent parenchymal infection distal to obstructing bronchial carcinoma—a condition similar in all respect to that which they believe obtains in lobar pneumonia—but in these cases, no matter of how long duration, there have been present the signs of atelectasis, never those of pneumonia.

The authors have cited references to the effect that in pneumonia the increase in density on the roentgenogram appears first at the periphery, and they have stated that the same occurs in bronchial obstruction. They have not presented evidence that this is so. In the only early instance of atelectasis which I have seen there was present an even, slight increase in density over the whole lobe. They hold that the preponderance of alveoli at the periphery and of large bronchi at the hilum accounts for this. It is a well recognized fact that the density of the walls of the large bronchi compensates for the lack of density of their lumina. Moreover, if, as the authors contend, the large bronchi are filled with viscid secretion, it is inconceivable that they would contribute to a decreased density.

The authors have laid great stress on the early decrease in breath sounds in pneumonia and on the deviation of the mediastinum and diaphragm toward the lesion, maintaining that these can be explained satisfactorily only on the basis of bronchial obstruction. I do not believe that this is so. The interstitial cellulitis, starting as it does at the hilum, certainly stiffens the lung, renders it less elastic and thus decreases its expansion. The pain incident to the pleurisy works toward the same end. The respiratory murmur must be diminished accordingly. There is rarely the total suppression of breath sounds which would necessarily be present were the bronchus occluded.

As to the displacement of the mediastinum and diaphragm, it is not necessary to conclude that the main bronchus is obstructed merely because a consolidated is smaller than an aerated lung. It is conceivable that a consolidated lung is simply smaller than the normal lung. If, however, atelectasis is to be considered as the cause of the decrease in size, it is much more reasonable to believe that it is caused by occlusion of the bronchioles. Since the time of Fauvel it has been recognized that patchy areas of atelectasis of this origin occur frequently in pneumonia.

A further difference between lobar atelectasis and lobar pneumonia is that in the former there is always some obvious impediment to the evacuation of secretions. In the latter, there is no hindrance to cough, and the sputum raised comes up easily. It is difficult to conceive how virulent pneumococcal sputum could collect in quantities sufficient to obstruct a large bronchus, the part most sensitive to stimulation, without inducing more cough than is usually present at and before the onset of pneumonia. Their hypothesis that there is an inhibition of ciliary action in pneumonia is an hypothesis, and the statement that such an inhibition would so hinder evacuation as to allow plugging of a main bronchus belongs in the same category.

I believe that the theory is still very much a theory, that there are no facts that the authors present in its support which cannot be explained equally well on other bases, and that the experiments which they have performed do nothing to strengthen the case. I shall be unable to believe the theory until it has been demonstrated clinically and experimentally that bronchial breathing, increased tactile fremitus and whispered and spoken voice are compatible with obstruction of the bronchus supplying a lobe.

## PERFRINGENS ANTITOXIN AND EXPERIMENTAL INTESTINAL OBSTRUCTION \*

J. C. OWINGS, M.D.

AND

C. A. McINTOSH, M.D.†

BALTIMORE

Though there had accumulated an extensive literature on the subject of anaerobes, and though much had been learned about gas gangrene from a surgical point of view, not only before but during the World War, it was only in 1918 that a polyvalent antitoxic serum<sup>1</sup> was elaborated both for preventive and for curative use. In 1917, Bull and Pritchett<sup>2</sup> proved beyond all doubt the practical value of *B. welchii* antitoxin, and thus led the way for the production of the polyvalent serum that contains not only the antitoxin to *B. welchii*, but to *Vibrio septique* and *B. oedematis* as well. It has been chiefly since the war, therefore, in the rare occasions of civil practice, that the more efficient serum has been employed. It would seem from a fair number of cases reported that the efficacy of antigas gangrene serum was comparable to that of the antitoxin of *B. diphtheriae*.

While it is clear that there would be a specific indication for the employment of an antigas gangrene serum in the case of an obvious anaerobic infection of a wound, there are many other conditions in which it has been employed when the indications are not so obviously defined. In the main, these consist of the following: intestinal obstruction, gangrenous appendicitis, general peritonitis, pulmonary gangrene, etc. A polyvalent serum has been used in France for some time as a therapeutic agent in cases of gangrenous appendicitis, and the results appear to indicate a definite reduction of mortality. The theoretical basis for its use was founded on the finding of *B. welchii* in many cases of acutely diseased appendixes. An examination of the American literature reveals that the use of the same type of serum has been followed by favorable results in a corresponding variety of cases.

Prompted probably in large measure by these successes and based on both clinical and experimental investigation, there has recently

appeared, in a convincing article by Williams, a British surgeon,<sup>3</sup> a new hypothesis that the toxemia in cases of intestinal obstruction, whether organic or secondary to peritonitis, resulted, in part at least, from the absorption of the toxin of *B. welchii*, due to the proliferation of this anaerobe in the stagnant contents of the small intestine. In support of this hypothesis, evidence is given of the proliferation of *B. welchii* in the small intestine in cases of intestinal obstruction and peritonitis in human subjects and in these diseases experimentally produced. Evidence of the presence of *B. welchii* toxin and its absorption is also given, while the beneficial results from the therapeutic test of the hypothesis, by giving *B. welchii* antitoxin in a series of cases of appendicular appendicitis and acute intestinal obstruction, are also reported.

The employment of such an antitoxic serum in the grave conditions of acute intestinal obstruction and general peritonitis with what appears to be a decided fall in the mortality, is surely a great achievement. In an effort to substantiate the foregoing hypothesis on an experimental basis alone, we have undertaken certain investigations, the outcome of which has convinced us that much has yet to be done to explain the toxemia of the diseases just mentioned.

#### EXPERIMENTAL STUDIES

*I. B. Perfringens Antitoxin in Dogs with Simple Intestinal Obstruction.*—In forty-two small dogs, a simple intestinal obstruction was induced high up in the small bowel. Each animal was given  $\frac{1}{4}$  grain (0.016 Gm.) of morphine and ether anesthesia before operation. In each instance the bowel was doubly clamped about 6 inches (15.24 cm.) below the duodenaljejunal junction, cut across, the ends turned in by the Parker-Kerr method and reinforced by a double row of mattress sutures.

Eleven of these animals were used as controls. Nine were given horse serum daily. Ten were given injections of diphtheria antitoxin, while the remaining twelve were given daily subcutaneous injections of *B. perfringens* antitoxin. The first group or control animals was not given any treatment. All were allowed to drink as much water as they chose. They were offered food, but rarely ate.

The second series was given normal horse serum, 5 cc., each day, subcutaneously. The serum used was supplied by the Parke Davis Company and contained a preservative.

The third group was given 5 cc. of diphtheria antitoxin that contained 650 units per cubic centimeter. The injections were also made daily and subcutaneously.

The final series of dogs was given daily injections of 5 cc. of perfringens antitoxin, which was procured from the Mulford Company of Philadelphia, and was standardized so that 1 cc. of the serum would neutralize 1,000 minimal lethal dose of perfringens toxin.

The duration of life of each of these animals is shown in table 1. The injections of serum were begun on the day after operation. It will be seen that three animals in each series, except that given the horse serum, were found at

3. Williams: Brit. J. Surg. 14:295, 1926.

autopsy to have some degree of peritonitis that must surely have shortened their lives. The peritoneum in the other thirty-three dogs was normal grossly. The average duration of life of those dogs without peritonitis in series D, it must be admitted, was slightly greater than in the others. This, however, is not the case when the animals with peritonitis are included. Finally, it is obvious that no material difference can be emphasized between any of the groups, and the dog that lived the longest, peculiarly enough, received diphtheria antitoxin.

II. *B. Perfringens* Antitoxin in Dogs with Isolated Intestinal Loop.—In five instances an isolated intestinal loop was made that contained a portion of the duodenum and jejunum, while the intestinal tract was reestablished by a lateral anastomosis. As a general rule such animals die from two to five days after the operation. At autopsy, there is found either a perforation of the loop, which is by far the more common occurrence, or a moderately distended one, unruptured. The death of an animal some days after such an operation and the absence of a perforation in the loop is, so far as we are aware, the best proof extant that a toxic substance is absorbed from the loop and is the lethal agent. In any experiment with an isolated loop, the contents of the loop will be found, after twenty-

four hours, to possess a toxin which it is supposed is the lethal agent, not only in these experiments but also in simple obstruction.

Each of the five animals so prepared was given 5 cc. of *perfringens* antitoxin subcutaneously on successive days, beginning twenty-four hours after operation. The duration of life of each animal was two, five, five, eight and thirteen days, respectively, with an average of 6.6 days. At autopsy each dog was found to have general peritonitis resulting from a rupture of the loop.

III. *Isolated Loop Toxin and B. Perfringens* Antitoxin Mixed and Injected Intravenously.—Loop toxin was procured by the following procedure: A duodenojejunal loop was made in the usual manner, and after forty-eight hours the animal was killed. The isolated loop was removed, incised and its contents added to 40 cc. of physiologic sodium chloride solution in which the loop was thoroughly washed. The material was then filtered through about six layers of gauze to remove any gross matter. The whole process would consume not more than from fifteen to twenty minutes when it was used for injection. To three control dogs, 2.5, 5 and 8 cc. were given intravenously. The same amounts were injected into three others, though to each there had been added an equal quantity of *perfringens* antitoxin and the mixture allowed to stand a few minutes. That is,

in the second group, one animal was given intravenously 2.5 cc. of the toxic fluid and 2.5 cc. of antitoxin; the second received 5 cc. of toxic fluid and 5 cc. antitoxin, and the third 8 cc. of each. All the animals became profoundly sick. They vomited, passed urine and feces. They behaved in the manner already described by many observers. As will be seen by table 2, only two animals lived, one that was much larger than the rest. All three animals that were given antitoxin with the toxic fluid succumbed in eight hours. The autopsies revealed the same pathologic condition as has been described elsewhere by other investigators who injected loop toxin into animals.

IV. *Isolated Loop Toxin Injected Intravenously into Dogs Immunized to Perfringens Toxin.*—Seven dogs were successfully immunized to perfringens toxin. This was accomplished in the same manner as has been done in rabbits and horses. Perfringens toxin was procured from the Mulford Company, Philadelphia, in two lots, one that contained 2 minimal lethal dose per cubic centimeter, and a second that contained 2.5 minimal lethal dose per cubic centimeter. An initial dose of 2 cc. of toxin was given subcutaneously. One week later 4 cc. were given, then 5 cc. the third week, and this repeated till the fifth or sixth week, when the dogs were found to have a moderate degree of immunity. Following the first subcutaneous injection, an area of induration and tenderness would appear at the

site and persist for a few days. In one or two instances no such areas formed, but these animals did not possess a natural immunity to perfringens toxin. The second, third and fourth injections brought forth smaller areas of reaction, so that when a definite immunity could be proved by a test of the dog's serum, little response was noted at the site of injection of the toxin.

At varying periods the dogs were bled and their serum employed to protect pigeons against lethal doses of the perfringens toxin. No attempt was made to procure a maximum degree of immunity in these animals, and for the most part a serum the strength of which was such that 1 cc. would protect against 25 minimal lethal dose was considered satisfactory. In fact, the actual strength of the serum of each animal was not determined, but a minimum of 0.1 cc. serum to neutralize 1 cc. of toxin was set as essential. The strength of each serum will be seen in table 3. In two dogs, it was below this level.

These animals with an active immunity to perfringens toxin were given injections of isolated loop toxin. The toxic fluid was prepared in the same way as that already recorded and each animal was given what was considered to be a minimum lethal dose for a normal dog of the same weight. In series A, table 3, three animals died following an injection of 5 cc. toxic fluid which was not lethal to the normal control dog. The fourth dog died almost immediately when it was given, some days later, 7 cc. of toxic fluid, which was also fatal to a control dog. In series B, table 3, 7.5 cc. is found to be a fatal dose for both immunized animals and the normal control. The three animals were dead in from three to four hours and showed the usual pathologic condition.

The seventh dog's serum did not possess as great powers of neutralization, and 1 cc. of serum would only protect against 2.5 minimal lethal dose. This animal died three hours after an injection of 10 cc. of toxic loop fluid. A similar quantity was fatal in a control animal in eight hours.

These experiments clearly show that dogs that are immunized to the toxin of *B. perfringens* do not possess any greater power of resistance than do normal animals to a minimal lethal dose of loop toxin.

V. *Isolated Loop Toxin Injected Intramuscularly into Pigeons Protected with Dog's Immune Serum.*—The experiments reported here were done in two series and the data condensed in tables 4 and 5. They are comparable to the procedure already reported in which toxic loop fluid was mixed with commercial antitoxin and injected into dogs intravenously.

The loop toxin was prepared in the manner already described. In the first series the serum was obtained from two dogs, M 81 and M 82. One tenth of a cubic centimeter of the serum from these animals was known to protect pigeons against 2.5 minimal lethal dose of *B. perfringens* toxin. One cubic centimeter of

the serum of these dogs, that is, sufficient antitoxin to protect against 25 minimal lethal dose of toxin, was injected into the pectoral muscle of each of six pigeons after it had been allowed to stand for some minutes mixed with 1 cc. of toxic loop fluid. Each of these pigeons was found dead in eighteen hours, as were two others that received 1 cc. of loop toxin alone.

In the second series, the serum of three other dogs was employed. The strength of the serum of each animal was the same as that in the first series. One cubic centimeter of this was given to each of three pigeons that also received 0.25 cc. of toxic loop fluid. Three other pigeons received 0.5 cc. of loop toxin and 1 cc. of serum. Two pigeons received respectively 0.5 cc. and 0.25 cc. of loop toxin alone. Of the eight pigeons that were given injections of loop toxin alone, all but one were dead in thirty-one hours. A control pigeon that received 1 cc. of dog's immune serum remained well. Two other pigeons that received 1 cc. of perfringens toxin were dead in twelve hours.

Something may be said about the area in the pectoral muscle into which was injected perfringens toxin and toxic loop fluid. When perfringens toxin was used, there was a distinct edema of the breast and the subcutaneous tissues appeared gelatinous and hemorrhagic. When loop toxin was injected, there was less local edema and no hemorrhagic exudate in the subcutaneous tissues.

VI. *The Degree of Anemia that Follows the Injection of Loop Toxin.*—Intravenous injections of sublethal doses of the toxic fluid obtained from isolated loops were given to ten dogs. The degree of anemia produced after the injection is best shown in table 6. In four dogs, sublethal doses of *perfringens* toxin were given intravenously. The degree of anemia in these cases is shown in table 7. In the former group it must be confessed that, though the dosage employed is said to be sublethal, a few dogs, not included in the table, died before the hemoglobin was determined after the injection. Again, it must be borne in mind that the material thus injected, containing toxin as it does, is also grossly infected, so that a considerable degree of error is introduced into these determinations. More or less on this account the method of determining the hemoglobin has been by the rough method of the Talquist scale.

In the case of the *B. perfringens* toxin, the dose was well below the lethal amount. Fifteen cubic centimeters were injected into each animal although the fatal dose is somewhere about 30 for a small dog, while those used in the experiments were rather large animals. Hence we feel that the percentage fall of hemoglobin, though greater than in the series in which loop toxin was used, is not as great as it probably would have been had a larger dose been given or a lethal one injected.

However, though the control series in this group of cases is small and the degree of anemia produced by the *B. perfringens* toxin not great, there is a definite difference to be noted between the two groups. In the series in which *B. perfringens* toxin was used, there was an average fall of hemoglobin of 25.4 per cent. In the series in which loop toxin was injected the average fall of hemoglobin was only 5.6 per cent. Admitting that the methods employed allow for a certain degree

of error and that the experiment in itself was rather crude, it would still appear that the hemolytic power of the perfringens toxin was definitely greater than that of the toxic substance or substances contained in an isolated intestinal loop.

## COMMENT

A further word or two must be said by way of explanation in some of the experiments described. In section I, it is observed that in one group of dogs with intestinal obstruction, series B, horse serum was injected into the animals. As perfringens antitoxin is made up largely of horse serum, it was necessary to determine the effect, if any, of this

 † Each cubic centimeter contains 25 minimal lethal doses for 350 Gm pigeon

foreign serum on the animal with intestinal obstruction. So, too, series C, the animals that received diphtheria antitoxin, offered a further opportunity to observe the effect of horse serum, but also of a serum rich in antibodies, though not of a type particularly related to the condition under investigation.

The reason for employing 5 cc. of perfringens antitoxin as a dose in the animals of series D with intestinal obstruction was because that quantity was estimated to give the animal a few more units per kilogram than that suggested by Williams to be given to human beings. The dogs used in these experiments were practically all about the same size and would weigh about 5 Kg.

It must be admitted, of course, that such an experiment as described in the first section is a rather crucial test, and the antitoxic serum is

called on to be of use in a condition which in the end must result in death if not relieved. The serum employed, too, contains antitoxin to *B. perfringens* alone. However, even though cognizance is taken of these two facts, it is to be doubted if the serum given these animals was of any real value in serving to prolong their lives.

In the neutralization experiments in which loop toxin is mixed with *B. perfringens* (Mulford) antitoxin and injected intravenously into dogs, the results are comparable to those in which loop toxin was mixed with immunized dog's serum and injected intramuscularly into pigeons. To each of these groups of experiments, as well as to any that deal with the isolated loop toxin, there is the following objection: Absolute proof is wanting that the toxin contained in isolated loops is the same as that absorbed from the intestine in cases of intestinal obstruction. However, should it be the toxin of *B. welchii* that is the lethal agent, then the dogs and pigeons just mentioned should have been saved. It is our feeling that one or many extremely toxic products are contained in these loops, and that they for the most part are little changed by attempted neutralization with *B. welchii* antitoxin.

Still another point to be made concerning the toxic loop fluid that we have employed is brought out in section IV and probably again in section VI. Two dogs, M 78 and M 86, that were immunized to *B. perfringens* toxin, received intravenous injections of loop toxin that were just less than the lethal amount. Though these animals were extremely sick following the injection and died in four and five days, respectively, the cause of death was not only due to the injected toxin, but also to a moderate degree of pneumonia that followed from the introduction of infected matter into the blood stream. However, had a slightly larger dose been employed this complication would not have been encountered, as is shown in series B of the same group of experiments. In section VI, too, is found another late result of injecting this grossly infected material. Dog M 109 was given an injection of 1 cc. of loop toxin intravenously. The hemoglobin of this animal fell more than did the others in this series. Nine days after this injection the animal, which had not appeared well, died rather suddenly. At autopsy, there was found an acute and extensive inflammation of the gallbladder with perforation, and general peritonitis.

A word or two may also be said about the response of the animal and the autopsy observations following lethal injections of loop toxin and perfringens toxin. To each of two dogs, weighing nearly 5 pounds (2.3 Kg.), there was given 30 cc. of *B. perfringens* toxin intravenously. One was dead in four hours, the other found dead in eighteen hours. In each case following the injection there was moderate ataxia, apparent weakness of the hind limbs, a dazed appearance and slow movements; finally the animal crept away to a corner to remain inactive. The

autopsy, besides degenerative changes, showed definite evidence of hemolysis, and bloody fluid was found in the cavities of the chest and the abdomen. There was no unusual congestion of the duodenum.

The description of a dog into which loop toxin is injected has been made on many occasions, but by way of contrast must be repeated here. The animal apparently soon experiences pain. He yelps and begins to run about the room aimlessly and confused. He falls shortly to the floor, where he passes feces and urine and vomits. The respirations are slow and labored. The autopsy does not show any signs of so extensive a hemolysis, and the intestinal mucous membrane is much congested and engorged, particularly in the duodenal area.

Not only do the responses seen in the animal vary, but also the pathologic conditions are not the same. A more important point than either of these is the great difference in the minimal lethal dose of the *B. perfringens* toxin as compared to the loop fluid. Generally, from 2 to 5 cc. of the latter, when injected intravenously, results fatally. In the two small dogs just mentioned it required 30 cc. of *B. perfringens* toxin given intravenously to each. The strength of this solution was such that each cubic centimeter contained 2 minimal lethal dose for a pigeon weighing 350 Gm.

Finally, it must be admitted that not only in the isolated loop but also in the obstructed small intestine, *Bacillus welchii* is present. In a bacteriologic study in a few instances, there was a definite increase in the number of these organisms, though the aerobes greatly predominated.

#### SUMMARY

1. The life of dogs with high intestinal obstruction was not prolonged by the use of *B. perfringens* antitoxin.

2. Evidence is presented to show that a neutralization of the toxic substance or substances contained in isolated intestinal loops is not effected by *B. perfringens* antitoxin in vitro or in vivo.

3. A minimal lethal dose of loop toxin is also fatal to a dog immunized to the toxin of *B. perfringens*.

4. A minimal lethal dose of loop toxin in dogs is decidedly less in amount than that of *B. perfringens*.

5. The hemolysis that follows the intravenous injection of *B. perfringens* toxin into dogs is much greater than that which results from the injection of loop toxin.

6. Dogs may be successfully immunized to the toxin of *B. perfringens*.

# CHOLECYSTOGRAPHY

## A GENERAL APPRAISAL \*

BYRL R. KIRKLIN, M.D.  
ROCHESTER, MINN.

Prior to 1924, the roentgenologic diagnosis of disease of the gallbladder, in spite of the achievements of a few roentgenologists, was not generally efficient or held in high regard. In that year, Graham and Cole <sup>1</sup> announced their discovery of calcium tetrabromphenolphthalein as a cholecystographic agent. During the four years that have elapsed since then, cholecystography has become indispensable for routine examination, and a voluminous literature testifies to the vivid interest aroused by the new method. Cholecystography has been one of the most remarkable advances in medicine, and, although Abel and Rowntree <sup>2</sup> had previously shown that phenoltetrachlorophthalein was eliminated chiefly in the bile, it was Graham who first applied this principle to visualization of the gallbladder with the roentgen ray.

As the calcium salt proved to be somewhat toxic, Graham soon abandoned it for the sodium salt of tetrabromphenolphthalein. Then Whitaker and Milliken,<sup>3</sup> early in 1925, advocated the use of sodium tetraiodophenolphthalein on the ground that it produced fewer reactions and could be given in smaller doses than the bromine equivalent. Graham had tried the iodine compound almost at the beginning of his work, but because of impurities the drug had proved unsatisfactory. Indeed, he and his co-workers experimented with an impressively long list of compounds before their first publication.

In all the early work with cholecystography, the drugs were given intravenously. In February, 1925, Menees and Robinson,<sup>4</sup> employing the bromine compound, were the first to administer a cholecystographic

substance successfully by mouth, and they were soon followed by Whitaker and Milliken,<sup>5</sup> who reported the oral use of the iodine compound. Attention was then directed to devising satisfactory methods of oral administration and avoiding unpleasant reactions. The drug was given in stearin coated pills, in keratinized capsules and finally in plain capsules. Stewart<sup>6</sup> tried administration through the duodenal tube. Carman and Kendall dissolved the iodine compound in water, precipitated it in colloidal form with citric acid or fruit juices and administered it in the liquid state. While fresh the mixture was palatable and not nauseating, but was so unstable that the experimenters abandoned it without publishing their experience. Diiodocinchophen, brought forward on the Continent in 1926 by Pribram,<sup>7</sup> was given a brief trial in America because of reports that grave reactions had followed its use. In the following year, Kendall and I<sup>8</sup> reported the synthesis and employment of di-iodo-di-ethyl-ether of di-sal-icylphthalein, which proved to be satisfactory, but it is so difficult to produce that it is not available in quantity. Last year, Fantus<sup>9</sup> advocated employment of a colloidal preparation of the iodine compound. Recently, Levyn and Aaron<sup>10</sup> found that this drug can be given in liquid form by dissolving the dose in a small amount of distilled water and adding from 240 to 300 cc. of grape juice. This is not a stable compound, and they recommend dissolving the dose in distilled water and then adding enough malic acid exactly to combine with half of the sodium, thus presumably transforming the unstable di-sodium salt into the stable monosodium salt. This solution can be kept indefinitely and grape juice added before taking. At the Mayo Clinic, more than 500 patients have received 4 Gm. of tetraiodophenolphthalein in simple fresh aqueous solution with instructions to add grape juice and take it after the evening meal.

Nausea has rarely followed; flocculi of unabsorbed dye are seldom noted in the bowel, and the technic appears to excel any yet proposed for oral administration.

Much discussion has been devoted to the relative merits of the intravenous and oral methods. Graham and his associates,<sup>11</sup> including Sherwood Moore, strongly prefer the intravenous use of the dyes, and employ sodium phenoltetraiodophthalein, the isomer of sodium tetraiodophenolphthalein. Smaller doses of this drug are required, and it serves as a test of hepatic function as well as a cholecystographic medium. Graham and other proponents of the intravenous method felt that the oral method is not reliable unless the result indicates a normally functioning gallbladder, and that otherwise the data should be checked by an intravenous test. They were supported in their views by Case,<sup>12</sup> Blaine,<sup>13</sup> Zink,<sup>14</sup> Boardman,<sup>15</sup> Verbrycke<sup>16</sup> and others. On the other hand, most examiners in America are employing the oral method. While intravenous administration makes it certain that a full dose has been introduced into the circulation and excludes any question of absorption, occasional serious reactions, even in the hands of experts, make one hesitate to urge its use as a general routine. Although the intravenous method is carried out as an office procedure by a few examiners, it is generally held that the patient should be hospitalized; this has the disadvantage of increasing the patient's expense materially. While contraindications to intravenous administration of the dye have been advanced, it would seem from the work of Maddock and Whitaker<sup>17</sup> that contraindications have been overemphasized, especially that of biliary obstruction.

The oral method has no risks or contraindications, and it is easily employed. I have not found records of any serious reaction from its

use, although nausea, purging or vomiting occur occasionally. Some of the objections urged against the oral method are: (1) the patient may fail to take the drug as instructed; (2) the dye may be vomited shortly after it is taken; (3) its passage into the bowel may be retarded or prevented by pyloric obstruction, and (4) it may fail to be absorbed adequately or at all by the intestine, the fecal content producing dense shadows overlying the gallbladder. Experience indicates that none of these objections is important. At the Mayo Clinic, sodium tetraiodophenolphthalein has been given orally as a routine to thousands of patients during the last three years. For several months a selected group of cases, now numbering more than 200, showing positive data with the oral test, have been checked by intravenous injection. The results, as well as those obtained from similar comparisons by other observers, show that the accuracy of the oral method compares favorably with that reported by partisans of the intravenous technic. Even if a difference in accuracy of 1 or 2 per cent is granted, one is scarcely warranted in insisting on intravenous administration.

#### DIAGNOSTIC EFFICIENCY OF CHOLECYSTOGRAPHY

Statistics published in America estimate the diagnostic efficiency of cholecystography at from 78 to 100 per cent.<sup>18</sup> Aside from differences due to the personal equation, reasons for the variance will be found in: (1) a lack of exact knowledge as to the line of demarcation between the normal and abnormal gallbladder from the standpoint of the surgeon, anatomist, physiologist and histopathologist; (2) differing conceptions as to cholecystographically normal and abnormal gallbladders; (3) the use or nonuse of clinical data in arriving at cholecystographic diagnoses, and (4) differences in the character of the material on which the computations are based and in the methods of analysis.

According to Judd,<sup>19</sup> surgeons are called on to operate for disease of the biliary tract more often than for any other abdominal lesion, and he considered it of the first importance to determine who shall say whether the gallbladder is diseased, the clinician, surgeon, roentgenologist or pathologist. His expression is fully warranted by the confusion which prevails. While decision whether the gallbladder shall be explored surgically depends primarily on the clinician, he in turn looks to the roentgenologist and surgeon for advice, and all eventually appeal to the anatomist, physiologist and pathologist for basic knowledge. Each link in the chain has its points of strength and of weakness.

---

19. Judd, E. S.: Cholecystitis, *Northwest Med.* **25**:167, 1926; **26**:377, 1927.

Thanks largely to cholecystography, the anatomists have learned that, as George<sup>20</sup> pointed out long ago, the gallbladder does not have a fixed position, but, like many other abdominal organs, its form and position vary greatly and are related to habitus. From the physiologist, more exact information is desired as to the functional behavior of the gallbladder and its alteration by nonpathologic states, for the study of which cholecystography itself offers a facile means. Mann<sup>21</sup> and other physiologists considered the gallbladder a rather temperamental organ susceptible of influence by many remote conditions. Mann's work indicates that a degree of stasis occurs during pregnancy. Boyden<sup>22</sup> concluded from his studies that the gallbladders of women empty more quickly than those of men. Plummer,<sup>23</sup> interested primarily as a clinician, observed that a certain type of patient, characterized by easy fatigability, achlorhydria and a low basal metabolic rate, is likely to respond eccentrically to cholecystography, the shadow frequently being faint or absent, although clinical evidence of cholecystic disease is lacking.

More precise definitions of cholecystic disease are needed from the pathologist. It is a moot question whether pericholecystic adhesions necessarily imply a pathologic condition of the gallbladder. Certainly such a gallbladder may concentrate dyes normally, and granting that it is abnormal anatomically, the new question arises whether the abnormality constitutes disease of clinical moment. On the other hand, the capacity of concentrating dye is not invariably diminished by definite disease, nor is there a constant relation between the degree of concentration of bile and that of cholecystographic media, as shown by Caylor, Bollman and myself.<sup>24</sup> The significance of petty anatomic changes which are visible only with the microscope is also open to argument. In many instances the changes, which have conveniently been designated as "cholecystitis graded 1," signifying cholecystitis of minimal degree, possibly represent ancient disease now healed or quiescent; in other instances, abnormalities of equal extent are meaningless, and the gall-

bladder can be rated as normal. It is an odd fact that most patients with cholecystitis graded 1, who have at any time had marked symptoms suggestive of cholecystitis, profit by cholecystectomy, while most of such patients whose symptoms are slight and atypical do not derive benefit from the operation. Obviously there is a point at which even the microscope fails to distinguish with certainty between health and disease, or at least fails to throw light on the clinical import of slight departures from the normal.

The warmest advocates of cholecystography have no reason to complain of the general attitude of clinicians toward the method, for few of the latter have offered criticisms of the procedure. Eusterman,<sup>25</sup> however, insisted that the roentgenologist should never assume the responsibility of diagnostician, valuable as the aid of the x-ray may be, and asserted that it is out of harmony with medical experience to expect cholecystic disease to be diagnosed infallibly by any single laboratory test.

In view of the basic defects in knowledge of the function and pathologic changes of the gallbladder, it is surprising, not that cholecystography is sometimes in error, but that it is so rarely wrong, and that the distinctions between normal and abnormal responses to the test as first laid down by Graham should be maintained with so little alteration. However, individual examiners vary considerably in their application of these criteria and in stringency of interpretation. For my own part, I am constantly inclined toward a more liberal appraisal of the normal and a more conservative judgment of the abnormal. This attitude is in consonance with the fact that cholecystography is a test principally of the dye-concentrating ability of the gallbladder and, except in patients with stones, not a means of demonstrating pathologic changes directly. Further, it is a test of function at the moment, without any obligatory relation to previous disease or future recurrences. In my own work, it is the custom to construe the cholecystographic data without any knowledge of the clinical facts in the case. Acquaintance with the clinical history may assist the examiner in making diagnoses when the roentgenologic evidence is scanty or equivocal, but such diagnoses are not roentgenologic. Eventually, all the facts from all sources should be weighed together, but this correlation belongs properly to the clinician.

Perhaps the most difficult item of cholecystographic interpretation is the determination of what constitutes normal density of the cystic shadow. Density not only varies with the drug employed and the quantity prescribed but has a considerable range of variance under

---

25. Eusterman, G. B.: Limitations of Cholecystography with which Physicians Should be Familiar, *J. A. M. A.* 90:194 (Jan.) 1928.

comparable conditions, and the personal equation enters inevitably into judgment. The density is seldom of the ideal quality depicted in published illustrations. Ordinarily, the shadow is denser at the sixteenth hour than at the fourteenth; at the twentieth hour, a fatty meal having been taken in the meantime, the shadow will most often have disappeared. But the sequence is not inflexible, and the shadow may be densest at any one of the three periods. As a rule, the shadow will be slightly larger at the second period than at the first, although the reverse is sometimes true; here, again, the sequence is less important than the fact of changing size. In asthenic persons the gallbladder is likely to be long, slender and perhaps pointed; in the sthenic or hypersthenic habitus, it is usually short and rounded; exceptions are numerous, and the general form is without significance. Its position is widely variable, and it may be seated high or low, mesially or laterally, without meaning. The shadow should be homogeneous in the sense of not having persistent thin areas or dense spots, although a higher concentration of dye at the fundus is common during the final stage of emptying. On the whole and with few exceptions, judgment of any particular quality of the shadow should be based, not on its worst, but on its best, appearance at any stage of the examination.

#### INDICIA OF CHOLECYSTIC DISEASE

After four years' experience, observers differ, of course, as to the value of the various signs of disease, and it would be difficult to summarize general opinion. I shall therefore emphasize only those signs which I have found trustworthy.<sup>26</sup> If one assumes that lapses of technic can be excluded, the reliable indicia of cholecystic disease comprise but three varieties of abnormality in the shadow of the gallbladder: (1) absence of shadow, (2) faintness of the shadow and (3) mottling of the shadow. Although absence of a shadow may result from extensive disease of the liver, failure of the dye to be absorbed by the intestine, or defects in the mechanism regulating the bile pressure, experience has proved such causes to be rare, and this negative sign can be construed consistently as an index of disordered function. I would insist strongly on the necessity of caution in pronouncing the shadow to be faint, for normal concentration has a wide latitude, and only a shadow which is scarcely visible at all periods can safely be considered faint. Mottling of the shadow, by either denser spots or translucent areas, is significant of stones when superposed intestinal gas, calcified glands, ossifying costal cartilages or transverse processes can be barred. If the gallbladder remains unchanged in size throughout,

---

26. Kirklin, B. R.: *Efficiency and Limitations of Cholecystography*, Boston M. & S. J. 197:1487, 1928.

especially if the shadow is constantly faint, the patient should be reexamined without dye, for in such instances the shadow may result from disease of the gallbladder and not from drug-laden bile.

Irregularities of contour seldom denote intrinsic disease. A marked serration of the border, the shadow being fixed in position and in the same situation at all periods, has been seen rarely in cases showing dense adhesions, and a single band of adhesion may produce an incisura with hour-glass deformity of the gallbladder. As the function of concentration is preserved, the gravity of the condition is doubtful and its cholecystographic manifestation is rare, for in most instances adhesions, however dense, do not cause deformity of contour. Angulation at the neck of the gallbladder has no pathologic import. The large or small size of the gallbladder is without significance. Occasionally the cystic shadow does not appear until the twentieth hour, but on reexamination the cholecystograms almost invariably follow the usual sequence, so that the delayed appearance of the shadow was probably due to the patient's failure to comply with instructions. While further experience may prove that delayed filling and its opposite, retarded emptying, are indicative of disease, I have not yet been able to attach importance to either alone.

Since cholecystography is preeminently a test of the ability of the gallbladder to receive and concentrate dye-laden bile and since this capacity does not have a constant relation to health or disease, it would seem that the examiner's report to the clinician should be in terms of function rather than of anatomic condition. Accordingly, at the Mayo Clinic reports are now made in one of three forms: (1) normally functioning gallbladder, (2) poorly functioning gallbladder, when the shadow is persistently faint, and (3) nonfunctioning gallbladder, when a shadow of the viscus is not seen. Evidence of stones may be associated with any of the three types and is so reported.

Differences in material and in methods of analysis undoubtedly account for some of the divergent statistics regarding the accuracy of cholecystographic diagnosis. For example, Graham's and Sherwood Moore's computations, as the authors have been careful to point out, have been based on one group only, those cases in which the cholecystographic data indicated disease and the gallbladder was removed at operation. Their estimate of 97 per cent accuracy is not extravagant and agrees substantially with the results in this group at the Mayo Clinic and elsewhere. This percentage cannot be taken, however, as indicating the average efficiency of cholecystography, since account is not taken of cases in which the cholecystographic symptoms are normal and the ratio of error is highest. Complaint has been made also that high valuations of cholecystography occasionally have been based on a small series of cases. Yet when analyzed on similar bases, the statistics are not really

discordant. They are highly complimentary to the method, and experience at the Mayo Clinic may be cited as probably representative.

Cholecystography at the Mayo Clinic has increased progressively in accuracy during the last three years. During that time, there were 17,289 examinations with 2,476 patients operated on. In 1925, the general accuracy of all cholecystographic diagnoses, including those on normal persons, was 79 per cent; in 1926, it was 84 per cent, and in 1927, 90 per cent.

During 1927, 5,705 patients were examined. In 1,967 (34.4 per cent) the cholecystographic data indicated disease, while in 3,738 the data pointed to a normally functioning gallbladder. Of the whole number of patients examined, 869 were operated on, either for disease of the gallbladder or for an abdominal lesion. Among the 869 patients with and without cholecystic disease, cholecystography had forecast the condition found at operation in 778 (90 per cent).

Conditions reported by the surgeon or pathologist were as follows: diseased gallbladder with stones, 422; diseased gallbladder without stones, 147, and other abdominal lesions, 300.

In 97 per cent of 422 cases in which gallstones were found, the cholecystograms indicated a poorly functioning or nonfunctioning gallbladder. In only 170 cases (40 per cent) were gallstones manifest as dense or translucent areas and diagnosed as stones.

Of the 147 cases in which the gallbladder was diseased but did not contain stones, there was evidence of disturbed function in 100, while in 47 the gallbladder was apparently deporting itself normally.

Among the 300 cases in which the gallbladder was pronounced normal by the surgeon and pathologist, cholecystograms were normal in 90 per cent.

To analyze the 869 cases from the standpoint of the various types of roentgenologic data, the series may be divided into four groups: (1) nonfunctioning gallbladder with and without stones, (2) poorly functioning gallbladder with and without stones, (3) normally functioning gallbladder with stones and (4) normally functioning gallbladder without stones.

In the first group were 317 cases in which the gallbladder was reported to be nonfunctioning. In 243 of these (76.6 per cent) the diseased gallbladder was found to contain stones at operation; in 57 (18 per cent) the gallbladder was diseased but did not contain stones, and in 17 (5.4 per cent) the gallbladder was considered normal by the surgeon or pathologist or by both. In short, in 95 per cent of the cases of nonfunctioning gallbladder the condition was confirmed at operation.

In the second group were 212 cases in which the gallbladder functioned poorly. In 156 of these (73.6 per cent) cholecystic disease

with stones was found at operation; in 43 there was definite disease of the gallbladder but no stones, and in thirteen the gallbladder was normal. The total accuracy of diagnosis in this group was 94 per cent.

In the third group were 9 cases interpreted as showing a normally functioning gallbladder with stones, in all of which the condition was confirmed at operation.

In the fourth group, in which a normally functioning gallbladder was reported, there were 331 cases, and it is in this group that the highest percentage of error occurred. At operation the gallbladder was pronounced normal in 270 cases, but in 47 it was definitely diseased, and in 14 others it contained stones. When the films were reviewed, a few instances were found in which the patient had moved or the films were of substandard quality so that by reexamination stones might have been discovered, but in most of them, as well as in the cases showing diseased gallbladder, there was no reason to change the original roentgenologic diagnosis. That the normal cholecystogram should be relatively less reliable than the abnormal is contrary to general expectation. It is compatible, however, with the work of Caylor and Bollman,<sup>27</sup> who have shown that the function of concentrating bile may be preserved or even enhanced in spite of advanced disease of the gallbladder. They have shown that in certain types of cholecystic disease the entire organ is not necessarily involved; there may be hyperfunctioning areas, impaired areas and normal areas.

In addition to the foregoing analyses, I have reviewed the cases showing positive cholecystographic data in which the gallbladder was later removed. It is on a similar group that Graham's figures are based. Among the 505 cases in this group, 496 showed gross evidence of cholecystic disease, while nine showed only microscopic changes indicating a mild cholecystitis. If one assumes for the sake of accurate statistics that these nine cases represented normal gallbladders, the accuracy of diagnosis in this group was 98.2 per cent. In all of these cases, the drug was given orally.

#### SUMMARY

While no one can speak with full authority as to the present status of cholecystography in America, the following might be regarded as outstanding features:

1. Notwithstanding its brief history, cholecystography has attained unusually wide vogue and has achieved a diagnostic excellence equal or superior to that of accepted tests for other diseases.

2. The method is so efficient already that further improvement will probably be gained only slowly and by strenuous effort. Lines along

---

27. Caylor, H. D., and Bollman, J. L.: Bilirubin Content in Gallbladder Bile in Cholecystic Disease, *Arch. Path.* 3:993 (June) 1927.

which advance may lie include the development of new cholecystographic compounds and improved technic of examination.

3. Like all laboratory tests, especially those applied with the x-ray, the greatest misfortune to cholecystography has been, not the scant criticism it has received, but the tendency to credit it with infallibility and to depend supinely on its verdicts.

4. In spite of the general efficiency of cholecystography, it has its limitations and is subject to errors of interpretation many of which will probably continue to be inevitable. Fear has been expressed that by erroneous diagnoses of disease the test will be made a pretext for unwarranted operations. Yet it is equally objectionable to make a normal cholecystogram the pretext for failure to operate when operation is indicated, and the negative diagnoses furnish the greater percentage of errors.

5. A keener realization that the diagnosis of cholecystic disease is ultimately a function of the clinician and not of cholecystography or any other laboratory test is urgently to be desired at home and perhaps abroad. Cholecystography is a remarkably able coadjutor, but, whatever it may reveal, the clinician cannot forsake his prerogative and duty to correlate the data with his own information, weigh the probabilities of disease, estimate its gravity and recommend appropriate treatment.

# THE RELATIVE EFFECTS OF DISTENTION ON DIFFERENT PORTIONS OF THE INTESTINE \*

C. A. DRAGSTEDT, M.D., PH.D.

V. F. LANG, M.S.

AND

R. F. MILLET, B.S.

CHICAGO

One important clinical and experimental observation has long been accepted, namely, that acute obstruction in the proximal small bowel, duodenum or jejunum is more rapidly followed by serious symptoms and death than acute obstruction lower down, in the ileum or the colon. This has been variously explained. It has seemed possible to various workers that in addition to other possible factors, this might be correlated with the susceptibility of the wall of the bowel to interference with its circulation by the distention usually resulting from the obstruction. Some years ago, we <sup>1</sup> stated:

Organs, such as the colon or stomach, which have in part a storage function are capable of very great distention without injury by reason of the arrangement of their blood supply. On the other hand, the small intestine, especially the duodenum, is capable of practically no dilatation. By reason of its investment in a tough, fibrous envelope and the position of its nutrient vessels, which are arranged parallel to its long axis, any distention of the duodenum must result in an immediate circulatory damage.

In a recent paper, Foster <sup>2</sup> stated:

In high level lesions the course is more rapid and severe because the intestine here has a high degree of irritability and distention is more rapid. Because of the anatomic construction of this area, necrosis appears more quickly from secretion and internal pressure.

It seemed to us that, in part at least, these explanations might be subjected to experimental demonstration.

Many writers at various times have referred to the seemingly obvious disturbance of circulation in the bowel wall accompanying distention. A few workers have made special studies on this problem and have brought out various significant facts.

Van Zwahlenburg,<sup>3</sup> in 1907, made certain observations on the blood flow in the bowel wall by means of a light within the lumen of the intestine. He observed that with distention of the intestine by a pressure of 30 mm. of mercury some capillary streams were arrested; at 60 mm., small veins were arrested, and in most veins the current was slow; at 90 mm., all blood streams were moving slowly, and many but not all currents were changing direction frequently; at 130 mm. pressure, all circulation ceased, and there was some oscillation of corpuscles but no progress. He concluded:

The demonstration seems complete that distention of the gut (or of other hollow viscera) interferes with the circulation in its wall, and allows infiltration and effusion to take place into its walls and lumen and any other open spaces which may come within its influence. The return circulation is retarded at comparatively slight pressures. Effusion follows, as in all obstructions to venous flow. As the average venous pressure in the intestine under ordinary circumstances probably varies from 4 to 10 mm. of mercury, any pressure beyond that will offer some resistance to the return current.

In 1926, van Bueren<sup>4</sup> studied the pathologic changes occurring in distended loops of bowel and found that the characteristic features were areas of hemorrhagic infarction on the antimesenteric surface of the intestine, with varying degrees of necrosis to perforation occurring in these areas depending on the duration of the distention.

In 1927, Gatch, Trusler and Ayers<sup>5</sup> studied the effect of intestinal distention on the circulation of the bowel by recording the effect of such distention on the rate of blood flow in the returning veins. Their observations in general were confirmatory of van Zwahlenburg's, but, in addition, afforded an estimate of the degree of circulatory impairment at different levels of pressure.

In none of these reports, however, is there any reference to the comparative effects that may occur in different portions of the bowel to the same pressures. In most instances there is no reference as to which portion of the bowel was used for the experiment. We have accordingly endeavored to compare by a variety of methods the effects of distention at different pressures on the circulation in the bowel, using for this purpose the duodenum, terminal jejunum to proximal ileum and the colon. Dogs were used in all the experiments.

Several experiments were performed by a method similar to that of Gatch, Trusler and Ayers, except that water pressure was used instead

of gas pressure, and heparin was used to prevent coagulation of blood. Under anesthesia, a loop of duodenum, of the lower jejunum or upper ileum, and of the colon were isolated, cannulas inserted into the main vein draining the loop and the lumen of the loop connected to the pressure bottle. In this way simultaneous determinations of changes in the venous flow from the three loops induced by changes in intra-enteric pressure could be determined. The results of ten observations on four dogs are shown graphically in the accompanying chart in which the venous return is expressed in the percentage of the original control rate of flow. It is shown clearly that increasing distention produces an increasing impairment of the venous return in all instances, but that the

Effect of intra-enteric pressure on intestinal circulation.

circulation of the duodenum is much more profoundly affected than any other portion of the bowel. Our results with the jejunum and ileum check closely the results of Gatch, Trusler and Ayers, and lead us to believe that the small intestine used by them in their experiments was either the jejunum or the ileum and not the duodenum. We were also able to corroborate their observation that there is a residual flow of somewhat varying amounts which no amount of intra-enteric pressure stops. This appears to be due, as they stated, to anastomotic vessels in the mesentery. It was our experience that prolonged distention gradually increased this flow of blood through the anastomotic vessels until it nearly equalled the original flow. Thus even when the entire intestine from the pylorus to the anus is distended at sufficient pressure

to prevent all blood flow in the intestinal wall, the volume of blood flowing into the portal vein seems to return nearly to its original amount.

Four experiments of the type used by van Zwahlenburg were also performed. Loops of different portions of the bowel were prepared and connected to a pressure bottle and manometer. A small cystoscopic electric light was inserted into the lumen through a small incision kept tightly closed by a purse-string suture and the vessels in the bowel wall watched with the aid of a hand lens and low power microscope. In three dogs it was found that the flow in the veins of the lateral wall of the intestine ceased in the case of the duodenum at a distention pressure of from 35 to 40 mm. of mercury, in the case of the jejunum and the ileum at a pressure of from 55 to 65 mm. and in the case of the colon at 95 mm. In the fourth dog the respective pressures required were 65, 95 and 140 mm. Thus, although considerable variation seemed to occur in the actual pressure required, in every instance the flow in the vessels of the duodenum was impaired at lower pressure than that required for the rest of the intestine. It was also apparent from these observations that the obstruction to the flow occurs in the wall of the intestine as suggested by van Beuren, and not in the adjacent mesentery.

A number of attempts were made to demonstrate the effect of distention on the intestinal circulation by injecting into the circulation (both intravenously and intra-arterially) various dyes, lamp black and India ink, after first distending the intestines to various pressures. No clearcut effects were noted, and no conclusions drawn. Varying degrees of staining were not readily detected. Complete absence of staining appeared only when distention pressures were sufficiently high to occlude the arterial supply. Staining seemed to be equally marked both when there was no distention and when distention was of sufficient degree to impair the venous return.

The previous observations were generally in accord that the duodenal circulation was more susceptible of impairment than that in the jejunum and ileum, and that in the jejunum and ileum more so than the colon. Three groups of experiments were then performed to see if corresponding pathologic changes could be produced demonstrating the same gradation of effect by maintenance of the pressure over fairly long time intervals. In the first group of eleven animals, the pylorus and anus were tied, and the entire intestine distended at a constant pressure, the anesthesia being maintained. At the end of the experiment the different portions of the intestine were examined and compared. The results are indicated briefly in table 1 in which the outstanding circulatory changes are graded according to degree. During the course of some of these experiments, incisions were made in the wall of the bowel at various places to note the hemorrhage. This was done to note the effect on arterial flow. It was frequently observed that at a given

pressure, with the duodenum pallid and the jejunum or ileum hyperemic, freed bleeding would occur in the latter with no bleeding from the duodenal wall.

In the second group of seven animals, the pylorus was tied off, the anus closed by double string suture and the entire intestine distended with mineral oil. The abdomen was then closed and the animal allowed to recover from the anesthetic. All of the animals died in from ten to forty-eight hours except two in which leakage at the anus had occurred and abdominal distention had disappeared. In the other animals, the entire intestine was dilated, but there was no material pressure in the lumen. It was apparent, of course, that at whatever pressure injected the pressure would fall practically to zero as soon as any loss of tone or relaxation of intestinal musculature occurred. In two of the

TABLE 1.—*Effect of Intestinal Distention of the Bowel Wall*

18	75-80	8	0	0	+	+	0	0	+	0	0	+	0	0

animals there was a marked pallor of the duodenum contrasting with a condition of marked hyperemia and hemorrhagic infarction in the jejunum and ileum, and an approximately normal condition of the colon. In the other three animals, there was no great difference between the different portions of the bowel.

In the third group of animals, the experiment was performed as in the second group except that the intestinal tract was distended with nitrogen using different initial distention pressures. It was felt that owing to the slow disappearance of this gas from the intestinal lumen, a continuous distention pressure would be maintained until the death of the animal. Even with a slight amount of absorption or leakage the pressure would fall but gradually. The results are indicated in table 2 in which again the main changes in the wall of the bowel are graded according to degree.

From these three groups in which the pathologic changes produced by prolonged distention at various pressures were studied, the following

observations seem warranted. At a certain low, apparently minimally effective pressure, varying degrees of circulatory damage from cyanosis to hemorrhagic infarction may be produced in the duodenum with little disturbance elsewhere. As the pressure increases, these same changes begin to become manifest in the jejunum and ileum, but are accompanied by pallor and anemia in the duodenum. With further increase in pressure these evidences of circulatory damage begin to become prominent in the colon, while anemia and pallor begin to appear in the jejunum and ileum. With still greater pressure it would appear that anemia and pallor would prevail throughout the intestine. These observations are in consonance with those in the preceding experiments and seem to indicate that the circulation, both arterial and venous, is more vulnerable to the effects of distention in the duodenum and progressively less so as the rectum is approached.

There appears to be an anatomic explanation for this difference in susceptibility according to the demonstration by Eisberg<sup>6</sup> that in the small intestine the vasa recta pierce the muscularis in the mesenteric quarters, while in the large intestine they pierce the muscularis in the antimesenteric portion. According to some preliminary studies that we have made on the dog's intestine, the location at which the vasa recta pierce the muscularis in the jejunum and the ileum is approximately midway between the arrangement in the duodenum and that in the colon. That is to say, that if we represent the cross-section of the bowel by the face of a clock with the mesenteric attachment at 6, the vasa recta pierce the muscularis in the case of the duodenum at approximately 5 and 7, at 3 and 9 in the case of the jejunum and ileum and at 2 and 10 in the case of the colon. The superficial disposition of the vessels seem to allow them to withstand better a certain amount of distention without interference with the respective blood flow.

6. Eisberg, H. B.: On the Viability of the Intestine in Intestinal Obstruction, Ann. Surg. 81:926, 1925.

CONCLUSIONS

1. Distention of the intestine interferes with the flow of blood in the vessels in its wall.
2. This interference is greatest in the duodenum and least in the colon.
3. This variation in susceptibility appears to be correlated with a variation in the distribution of the blood vessels in the wall of the intestine.

## WHAT IS OPERATIVE MORTALITY?\*

HAROLD B. WOOD, M.D., Dr.P.H.  
Epidemiologist, Pennsylvania Department of Health  
HARRISBURG, PA.

"Operative mortality" is a term frequently encountered in surgical literature and used, apparently, to include the proportion of deaths which occur soon after operations. The reports of the percentage of deaths which quickly follow operations and which are regarded as operative mortality vary so widely for the same operation by different surgeons that it is evident that there has been no attempt to standardize the expression nor to explain its meaning or inclusion. Some writers report "hospital mortality," and others simply "mortality"; the former is definite, the latter undefined.

Some variation in operative or in a definite chronologic mortality may be expected, but great variations should be explained as Jones has done<sup>1</sup> with Miles' reports on operations on patients with cancer of the rectum in whom the mortality varied from 9 to 36 per cent, depending on the mode of anesthetization. The operative mortality will, of course, depend on and vary directly with the proportion of cases which the surgeon regards as operable. It is also true that classes of patients vary, and one hospital may not receive patients from the same social stratum that patronizes another hospital. One class of patients delays seeking surgical assistance more than another, thereby increasing the danger of the development of complications and their earlier fatal consequences. The questions of racial and national characteristics of patients are factors. It seems unjust, therefore, to draw comparisons between different operators by their undefined figures alone. In reporting early operative mortality some brief explanations, including the complicating conditions which hasten death, would assist in determining the preferable treatments to be applied to the given diseases. Non-operable cases in which exploratory operations are performed should, of course, not be listed with the others, but studies of this type of case are desirable to determine better methods for earlier diagnosis and more effective means to secure the patients at earlier dates.

Hospital mortality and the total mortality in cases of cancer are slightly suggested by the results of some combined figures of all Philadelphia and Pittsburgh hospitals for 1927: cancer of the stomach, 37 per cent deaths in the hospitals; cancer of the breast, 13 per cent,

---

\* Submitted for publication, Jan. 23, 1929.

1. Jones, D. E., in discussion on Rankin, Fred: Colostomy and Posterior Resection for Carcinoma of the Rectum, J. A. M. A. 89:1965 (Dec. 1) 1928.

and cancer of the uterus, 13 per cent. The total number of deaths from cancer in these two cities that same year would raise the total mortality to 98 per cent for cancer of the stomach, 42 per cent for cancer of the breast and 35 per cent for cancer of the uterus; the last figures are irrespective of operation, as all death certificates do not state definitely whether an operation had been performed.

Postoperation mortality, which is not operative mortality, shows wide variations, as stated by Saltzstein<sup>2</sup> in a survey showing operative mortality after resection of the stomach to be from 27 to 46 per cent, after rectal resections from 27 to 49 per cent, after operations for abdominal cancer 40 to 50 per cent, with minimum figures down to zero after operations for cancers of the breast, 7 per cent after operations for gastric cancers and 3 per cent following those for cervical or rectal cancers.

To determine the postoperative length of life the original death certificates of persons dying of cancer during 1927 in Pennsylvania were consulted. The dates of operation are not always supplied as they should be. In this series of cases, patients having a single operation and those in whom the operation was a definite operation for a single organ were selected. Intestinal and hepatic cases were excluded. The list includes patients operated on for cancer of the esophagus, stomach, pancreas, rectum, breast, bladder and generative organs. There was a total of 1,079 deaths; 436 occurred within the first month and 878 within the first year. In the succeeding five years there were 88, 51, 21, 13 and 13 deaths, respectively. Forty-six, or 4.3 per cent, of the patients lived over three years, and 15, or 1.4 per cent, over five years. Collectively, the deaths occurring during the first four weeks after operation numbered 276, 85, 54 and 21, respectively. There were 42 deaths occurring the same day as the operation. The number of deaths each succeeding day during the first week were: 46, 46, 31, 39, 30, 20 and 23. The second week the number of daily deaths were: 19, 9, 12, 8, 13, 7 and 17.

These figures show that the mortality following operation for cancer was greatest during the first year, during the first month and during the first week: 26 per cent of the deaths occurred in the first week and 8 per cent within twenty-four hours.

Complicating conditions that appear to have a direct connection with the operation were recorded for 114 of these cases in which deaths occurred from cancer within a week of the operation. These conditions included acute heart failure in 21 cases, acute intestinal obstruction in 21, postoperative pneumonia in 20, shock in 16, peritonitis in 12,

---

2. Saltzstein, Harry C.: *The Average Treatment of Cancer*, J. A. M. A. **31**:465 (Aug. 18) 1898.

uremia and hemorrhage in 6, embolism in 3, acute gastric dilatation in 1, acute urinary suppression in 1 and thrombosis in 1. Such conditions, I believe, can be regarded as operative complications, due to and following operation. There were 86 other deaths with defined complications in hopeless cases in most of which the operations occupied but minor positions in hastening death. These complications included metastases and extensions, grave organic conditions in the heart, kidneys or other organs, diabetes, toxic goiters, anemia, toxemia, cachexia or senility. In most of these instances the laparotomy was only exploratory. Operation was not necessarily contraindicated in any of these cases, as there was at least some chance of helping the patient.

A consideration of some individual organs and the immediate causes of death in connection with them is worth while. Those organs on which the greatest number of operations were required were the stomach, pancreas, uterus, bladder, prostate, rectum and breast.

The stomach with the pylorus was represented in 277 dated operations for carcinoma. The first four weeks 90, 26, 20 and 7 patients died, totaling 143. Twenty-three died within the next month, 21 within the third, and so on. One-half the patients died within a month after operation: 49, or 17.6 per cent, lived six months or longer; 21 lived one year or longer; 10 lived two years or longer, and only 2 lived over four years, then died. There were 12 deaths the day of operation, 82 within the next seven days, 26 within the second week and only 14 the third week. The deaths within the first week were 34 per cent of the total. These few figures do not indicate the relative mortality following these operations for cancer, but do suggest how soon fatalities may occur.

The complications recorded with the cases of gastric cancers in which deaths occurred in the first week comprised the following conditions, which may be regarded as directly related to the operation: shock in 3 cases, hypostatic pneumonia in 7, acute myocarditis in 12, acute obstruction in 5, acute gastric dilatation in 2, uremia in 2, peritonitis in 4 and hemorrhage in 1, a total of 36 postoperative complications giving a mortality ratio of 13 per cent. The other complications with extensive metastasis and distinct inoperable conditions for which the laparotomy was exploratory in nature, included chronic myocarditis, nephritis and diabetes, and included 24 cases in which no complicating conditions were recorded on the death certificates. The extended metastases and organic degenerations had no connection with the operation which was done as a last resort in a hopeless case, but because of the 24 undefined cases the operative mortality resulting from these gastric cancers cannot be placed at 13 per cent for these operators.

Pancreatic postoperation deaths from cancer totaled 64; 30 occurred during the first week; 52 during the first three months, and none after

the tenth month. Acute cardiac dilatation, shock, perforation, intestinal obstruction, hemorrhage and peritonitis accounted for 15 of the 30 deaths during the first week; in 9 other certificates complications were not defined. Thirteen of the 30 deaths occurred within the first twenty-four hours after operation. Some of these laparotomies were diagnostic.

Deaths from uterine cancer, including cervical cases, numbered 98; 10 occurred on the day of operation, and 42 during the first week. Thirty-seven women lived over one year; 19 lived over two years; 7 lived over three years, and 2 died after six years. Shock in 4 cases, and hemorrhage, peritonitis, acute cardiac failure, uremia and suppression of urine accounted for 10 of the 19 defined complications occurring in early deaths. Twenty-three of the 54 deaths resulting from cancer of the ovary occurred during the first week after operation, acute heart failure accounting for half of the eight operative deaths. Twenty-nine of the patients with ovarian conditions died the first month after operation; 45 died the first year; 5 died the next year, and only 2 of 54 patients lived five years.

Prostatic cancer was represented by 68 patients dying postoperatively. Fourteen of these died the first week, 11 the second week and 32 more within six months. Seventy-three per cent of the patients died within six months, and 12 per cent lived a year; only two patients lived over two years. During the first week, shock and intestinal obstruction caused 5 deaths; acute myocarditis, toxemia and peritonitis each were the cause of a death.

Cancer of the rectum accounted for 106 deaths in this list of cases in which operation had been performed; 35 patients died within the first week after operation; 6 the second week, and 8 the third week. Forty-four died within the first six months, and 15 within the second six months. Fourteen, or 13 per cent, lived, but half of these died within a year; the remainder died within eight years. The immediate causes of 35 deaths occurring during the first week after operation included intestinal obstruction in 10, pneumonia in 5, perforation in 2, peritonitis in 2, shock in 1 and undefined complications in 8. These figures indicate a great risk from operation.

Cancer of the breast shows a much lower early mortality than any of the other cases herein listed. In a total of 210 postoperation deaths only 12 occurred the first week, and 26 the first month. During the first year 112, or 41 per cent, died; 38 died the next year, and 26 the third year. Twenty-six, or 12 per cent, lived more than three years, and 3 per cent over five years. One death occurred eleven and 1 twelve years after operation, and another cause of death was recorded as "carcinosis" thirty years after amputation of a cancerous breast. The causes of the deaths during the first week were acute cardiac dilatation,

pneumonia, cerebral embolus, shock, toxic goiter, apoplexy, chronic myocarditis and dementia.

The percentage of deaths occurring within the first week following operation was as follows: 29 from cancer of the stomach, 52 from cancer of the pylorus, 48 from cancer of the esophagus, 48 from cancer of the gallbladder, 47 from cancer of the pancreas, 6 from cancer of the breast, 17 from cancer of the uterus, 42 from cancer of the ovary, 9 from cancer of the bladder, 20 from cancer of the prostate and 33 from cancer of the rectum. These are not representative ratios because the number of cases in this report are so few, but they do suggest high immediate mortality for some operations for cancer and low mortality for others. If operative mortality is considered to include only deaths resulting from shock, postoperative pneumonia, hemorrhage, peritonitis, acute myocardial collapse, acute intestinal obstruction, urinary suppression and similar conditions having a direct bearing on or resulting from the operation, the operative mortality of these cases of cancer would be much lower than these figures, but they cannot definitely be determined from the incomplete death certificates, a considerable number of which name no complications and give no idea whether the cases were found to be inoperable or whether the operation had a direct bearing on hastening death.

These cases of cancer are far too few to establish a general chronologic mortality rate, but they do suggest certain conditions resulting from the operative work of a large number of surgeons. In no way do they indicate the mortality ratio of these operations. There is no definite way in a state survey to approach this important item. For instance, the Pennsylvania hospitals in a questionnaire reported admitting 1,065 patients with cancer of the breast during 1927, with 80 deaths resulting in the hospitals, and the state mortality records show 852 deaths from malignant conditions, 810 from cancer of the breast, but because of the incompleteness of the death certificates the number of these patients on whom operations were performed cannot be determined.

The chief object in mentioning in a surgical paper the operative mortality following some specific disease or operation is to determine correctable defects in technic or treatment. It seems essential, therefore, to describe not only the delayed deaths and the apparent and definite cures, but the early fatal results. It is presumptuous to record a patient as cured, as many hospital records show, if the patient leaves the hospital in apparently good condition. The reports in medical journals should detail at least the principal complications leading to death and make a distinction between those directly caused by or following the operation and those not related to the operation. Some of the former have been listed herein. The 17 deaths from shock in this series

occurred the day of operation, and at least some might have been foreseen and prevented. The cases of postoperative pneumonia developed up to the fifth day; the early ones were doubtless inspirational and unavoidable, but the late ones may have resulted from chilling. A recent English book on cancer of the rectum courageously admitted an operative mortality of 16.5 per cent and declared that one half of this percentage was due to sepsis. Eleven in this series of 106 cases of rectal cancers from Pennsylvania were fatal within twenty-four hours and 35 within a week; in not one was sepsis a factor, unless the two cases of peritonitis may be so regarded.

Finally, a survey has disclosed that many hospital records do not correspond with their death certificates; some show fewer, and others more, deaths than the state mortality records disclose. Death certificates also are notoriously incomplete and inaccurate. In the state in which this article is written, certified copies of over one half of the death certificates of adults are used as legal evidence. If all surgeons and hospital interns realized the importance of these certificates, they might be more particular in having the records reliable. Many antiquated forms of death certificates, printed and distributed years ago, are still being used. Every death certificate should give definite information as to whether or not an operation, and also an autopsy, was performed. If at any time there had been an operation for the particular disease causing or relating to death, the name of the operation and date should be recorded. No omissions concerning these questions should be allowed. From the carcinomas considered in this report there was a total of 4,696 deaths, and on only 1,061 certificates was the complete statement made that an operation had been performed on the definite date given, with the exception of a few cases in which two operations had been performed for the same disease.

#### SUGGESTED NEEDS

Operative mortality is an ambiguous term which needs a time limitation.

Death quickly follows operations because of a complication caused by, or directly related to, the operation, because another previous organic condition could not withstand the overload of the operation, or because the disease was an unrecognized, inoperable condition.

The fatal complicating conditions induced by the operation indicate for their prevention a need of greater improvement in surgical or nursing technic.

Operations done in the presence of numerous organic degenerations or conditions are a lottery, but are not necessarily contraindicated, as there is always hope. These complicating conditions should receive clinical, laboratory, roentgen and therapeutic attention.

By improved methods of examination, inoperable conditions are being recognized more and more without the performance of an operation.

More study of the actual causes of death is needed, and more ways should be devised to avert them. In reporting operative mortality, it is desirable that the physician should state the definite causes of death.

Reports of mortality should be standardized or defined to cover a certain period of time and to include or exclude certain described diseases, complications or conditions in order that other surgeons may draw parallelisms with their own experiences for the mutual benefit of mankind.

Death records constitute important statistical and legal evidence, and should be accurate and complete, stating all the facts.

# ACUTE SURGICAL CONDITIONS WITHIN THE ABDOMEN OCCURRING DURING INFANCY AND CHILDHOOD

A STUDY OF THREE HUNDRED AND NINETEEN CASES \*

EDMUND HORGAN, M.D.

AND

JOSEPH HORGAN, M.D.

WASHINGTON, D. C.

The acute surgical conditions within the abdomen that occur during infancy and childhood must be looked on as extremely important when one considers the high mortality rate in cases in which the condition is incorrectly diagnosed, treatment by surgical measures delayed or the patient allowed to go untreated. Nausea, vomiting of food or bile-stained mucus, crying on account of abdominal pain, visible peristalsis, abdominal rigidity, increased abdominal tension, an abdominal mass, decrease or absence of fecal stool, passing of bloody mucus from the bowel or fever and leukocytosis should attract one's attention to the abdomen instantly, and an investigation should be made to determine whether or not an acute surgical condition exists within the abdomen. The responsibility of recognizing such a condition rests with the family physician or the pediatrician who observes the sick child. The responsibility of promptly treating the patient lies with the surgeon called in consultation. Because the acute surgical conditions within the abdomen quickly cause nutritive disturbances, toxemia and death, the surgical consultant must be called early. It is deplorable to see a child with an intestinal obstruction of three or four days' duration, or with some similarly acute condition, brought into the hospital at the point of death, and to see the parents still hopeful that the child may be saved.

This study shows by statistical report the high mortality rate during childhood in cases of acute surgical conditions within the abdomen, and mentions some of the most frequent of these conditions. It is based on a review of 314 cases in children, from infancy to the age of 12 years, who were admitted to the Children's Hospital from January, 1924, to December, 1928. A few cases observed in private practice have been included, making a total of 319 in the series. We have observed the following conditions: acute appendicitis, intestinal obstruction, intussusception, peritonitis, abdominal tuberculosis, hypertrophic pyloric stenosis, congenital malformations such as occlusion of the duodenum

and of the bile ducts, failure of rotation of the colon and Meckel's diverticulum, abdominal tumors, abdominal injury and foreign bodies. Certain conditions, such as gastric hemorrhage, gastric ulcer, abscess of the liver, cholecystitis, perforation or hemorrhage from typhoid or paratyphoid fever and intestinal obstruction from parasites, were not observed.

## ACUTE APPENDICITIS

Acute appendicitis is the most common of the acute inflammatory conditions within the abdomen. The death rate from this condition is much too high. In the group of 236 patients operated on, there is a mortality rate of 84 per cent. The delay of the parents in calling a

12 . . . . .	14	1	7.1

physician or the delay of the physician in sending the patient to the hospital for surgical treatment was the cause of death in every instance. There was not a single death among the patients with acute appendicitis in whom diagnosis was made early and from whom the appendix was removed before gangrene set in. However, 114 patients, almost 50 per cent of the entire number, had gangrenous appendicitis, with or without rupture and with or without abscess, when admitted to the hospital. All the deaths occurred in this subgroup, which gives it a mortality rate of 17.5 per cent and makes the mortality rate in the group with appendicitis 84 per cent. Five patients in this subgroup were in such a serious condition when admitted to the hospital that they died within fourteen hours

after admission. If these five were eliminated, the mortality rate for the remaining cases would be 6.3 per cent. Many of the patients who died had been under the observation and treatment of physicians for several days. In some instances, in spite of repeated warnings to the contrary, the physician ordered castor oil or magnesium sulphate given to a child suffering from abdominal pain, nausea and vomiting; in other instances, ice bags were ordered applied to the abdomen, and the parents were led to believe that the disease could be "frozen out." On recognizing the possibility that a child has an acute abdominal condition, a physician should call a surgeon immediately. Laxatives and purgatives should not be given. The surgical treatment for appendicitis is laparotomy through a small muscle-splitting incision over the appendix.

appendectomy and closure of the wound if the appendix is not ruptured; appendectomy and drainage if the appendix is ruptured. An appendiceal abscess should be opened and free drainage established. Whether or not the appendix should be removed in the case of an appendiceal abscess depends on the conditions found (table 1).

## INTESTINAL OBSTRUCTION

Intestinal obstruction from stenosis, volvulus, peritoneal bands, tumors, inflammatory processes, and the like, is attended by an appalling mortality. In our group of cases of all varieties of intestinal obstruction, including intussusception, we show a mortality rate of 40 per cent, which is unquestionably too high and is more than likely due to

a failure to recognize the condition before the child has become too ill to stand an operation. Vomiting, abdominal distention, failure to expel gas or to pass fecal stools, dehydration and toxemia follow in rapid succession and lead to an early diagnosis if the signs and symptoms are carefully observed. An untreated patient with complete obstruction of the bowel will die. The surgical treatment consists in the subcutaneous or intravenous injection of physiologic solution of sodium chloride, laparotomy for the relief of the obstruction and enterostomy when indicated. Resection of the bowel may be necessary if gangrene is present. Eight of the seventeen children on whom operations were performed to relieve intestinal obstruction died, a mortality rate of 47 per cent (table 2).

#### INTUSSUSCEPTION

Intussusception occurs most often in infants, although it may occur in an older child. Its onset is characterized by sudden abdominal pain, usually in an apparently well child. The pain is accompanied by vomit-

ing and small stools, and later there is a failure to pass fecal stools. Blood-stained mucus may be passed from the bowel, or bloody mucus may be seen in the return from an enema. A tumor mass may be palpated in the right lower quadrant, or lying across the midportion of the abdomen. Later, abdominal distention, dehydration and toxemia may be observed. Surgical treatment is employed following subcutaneous or intravenous injection of physiologic solution of sodium chloride, and consists of laparotomy for the reduction of the intussusception, and resection of the bowel with anastomosis if the intussusception is irreducible or gangrenous. Among the thirteen patients operated on for the reduction of the intussusception, there were four deaths, a mortality rate of 30.7 per cent (table 3).

#### PERITONITIS

Peritonitis occurs most often as a secondary condition to an acute perforation, intestinal obstruction, intussusception, appendicitis, trauma, etc., and as a postoperative complication after laparotomy. As a pri-

many condition, it occurs occasionally as an infection from the blood stream or lymphatics. The surgical treatment for secondary peritonitis is preventive, and treatment for the condition that may cause it should be undertaken as early as possible. Patients with primary peritonitis are not treated surgically unless an accumulation of pus can be located. When pus is found, it is drained by a simple procedure in the most direct way. Intravenous and subcutaneous injections of physiologic solution of sodium chloride and dextrose, transfusion of blood, gastric lavage and enemas are employed to maintain the body fluids at a normal level and to prevent toxemia.

#### HYPERTROPHIC PYLORIC STENOSIS

Hypertrophic pyloric stenosis is observed most frequently in infants during the early weeks of life. When the symptoms begin the child nurses well, but all milk and water are vomited after one or two feedings. The vomiting is projectile. Very soon after the onset of symptoms there is a noticeable loss in weight, the stools get smaller and

TABLE 4.—*An Analysis of Thirty-Two Cases of Hypertrophic Pyloric Stenosis*

fewer and the vomiting continues. The upper part of the abdomen appears distended, and peristaltic waves of the stomach can often be seen passing across it. A tumor mass can often be palpated in the upper part of the abdomen to the right of the midline. Surgical treatment consists of gastric lavage, subcutaneous or intravenous injections of physiologic solution of sodium chloride, or transfusion of blood, followed by a laparotomy for the incision of the pylorus by the method of Fredet-Rammstedt. There were seven deaths among thirty-two patients with surgical conditions of pyloric stenosis, giving a mortality rate of 21.8 per cent. We believe that the mortality rate for hypertrophic pyloric stenosis could be reduced if the patients were referred earlier to the surgeon for operation (table 4).

#### CONGENITAL ABNORMALITIES

Congenital abnormalities, such as hour-glass contraction of the stomach and occlusion of the duodenum or lower part of the bowel, will produce symptoms during the first days of an infant's life. The surgical removal of the occlusion of the lumen and the reestablishment of its continuity are always done under most unfavorable conditions.

Nevertheless, an occasional patient survives, and the effort to save the infant should certainly be made. We should like to record one case of occlusion of the first portion of the duodenum, which occurred in an infant a few days old, and on whom operation was performed in another hospital. The constriction was excised and an anastomosis made over a catheter. The infant died within six hours after the operation, but at autopsy it was demonstrated that the occlusion had been removed and the continuity of the bowel had been reestablished. The child might have been saved had the operation been done a day or two earlier.

Failure of rotation of the colon favors the formation of volvulus, with a resulting intestinal obstruction. Volvulus from this abnormality

\* Also included among cases of intestinal obstruction, but not included among cases of congenital abnormality in table 8.

may occur at any time of life. We observed such a condition at autopsy in an infant who died from an intestinal obstruction. The child had been seen before death, but its condition was so serious that we considered an operation inadvisable. At autopsy we found the proximal half of the colon rotated only to the midline. There was a twisting on its mesentery of the proximal half of the colon, the cecum and a few feet of the small intestine. The surgical treatment for volvulus due to failure of rotation of the colon is laparotomy for the untwisting of the volvulus, and resection with anastomosis if the twisted segment of the bowel is gangrenous.

Congenital occlusion of the common bile duct prevents the bile from reaching the duodenum. The skin and sclera become yellow and later

almost bronze. The stools are clay-colored. The accumulation of bile and mucus above the point of obstruction will greatly increase the pressure within the duct. When the pressure in the obstructed duct becomes great enough to overcome the secretory pressure of the liver, marked damage to the liver takes place. Unless the bile duct or gall-bladder can be anastomosed to the duodenum or stomach, the infant will not live. Operation should be performed as early as possible after the condition is recognized.

Meckel's diverticulum does not cause symptoms if its tip is free and not inflamed. The tip, however, may be attached to the umbilicus by a cordlike remnant of the omphalomesenteric duct. A coil of intestine may become twisted about this cord; the lumen of the bowel may then become obstructed. The winding of the mesentery about the cord may cut off the arterial blood supply and the venous return, and as a

result the twisted segment may become gangrenous. If an inflamed tip of a diverticulum becomes attached to the bowel or to the mesentery, a loop will be formed through which a coil of intestine may pass and become obstructed. When at operation a Meckel's diverticulum is found to be the cause of an intestinal obstruction, the tip must be made free. This will relieve the obstruction but it will not remove the cause. Therefore, the diverticulum must be removed. Its removal is usually accomplished by clamping the base, and cutting off the diverticulum. The stump is inverted by suture (table 5).

#### TUMORS

Abdominal and retroperitoneal tumors may cause obstruction of the bowel and require surgical intervention for relief. A benign tumor may be removed, but a malignant one, such as a retroperitoneal sarcoma, is usually not removable. Only two cases of obstruction caused by

retroperitoneal tumor have been found in the series from the Children's Hospital. Elsewhere, we observed the case of a boy, aged 7, who had a partial obstruction of the colon caused by a large hydronephrosis which pressed on the splenic flexure (table 6).

#### ABDOMINAL TUBERCULOSIS

Treatment for abdominal tuberculosis is rarely surgical. In adhesive tuberculous peritonitis an obstruction may occur that would require surgical treatment. In this series, there are six cases of adhesive tuberculous peritonitis which required operation for relief from intestinal obstruction. In four cases enterostomy alone was sufficient; in two cases, however, it was necessary also to remove a collection of tuberculous pus from the peritoneum. The mortality rate was 33.3 per cent (table 7).

#### ABDOMINAL INJURIES

Abdominal injuries, such as falls or blows, may produce rupture of the liver, spleen, intestines, kidney or bladder. The occurrence of any one of these conditions may require surgical treatment. We had one patient, a schoolgirl, aged 8, who on being struck in the abdomen by a rock had a rupture of the middle colic artery with profuse abdominal hemorrhage. Laparotomy to tie off the bleeding vessels stopped the hemorrhage and saved the child's life.

#### FOREIGN BODIES

Most of the foreign bodies that reach the stomach pass through the bowel and are expelled from the rectum. If a sharp or pointed body perforates or becomes lodged in the bowel, or if an intestinal obstruction is caused, a laparotomy for the relief of the condition becomes necessary. In this study, we found two cases in which a safety-pin became lodged at the pylorus and would not pass. In each case it was necessary to perform a gastrotomy for the removal of the foreign body. Both patients recovered.

## CONCLUSIONS

In the Children's Hospital, Washington, D. C., a large percentage of the children admitted for treatment are colored. In this series the cases in the colored children (21 per cent of the total number) undoubtedly raised the mortality rate as a whole. For instance, 56 per cent of the cases of acute appendicitis in the colored children were gangrenous with rupture or ruptured with abscess; there was no case of gangrene without rupture or abscess. Forty-five per cent of the cases in the white children were gangrenous, but the number with rupture or abscess was

relatively smaller (39 per cent). The mortality rate for this group of cases of gangrene with rupture and rupture with abscess was 25 per cent in the colored and 16 per cent in the white children. Four of the five patients who died within fourteen hours after being admitted to the hospital were colored; all four died within seven hours after admission. In three cases of intussusception in colored children there were two deaths, while among the white children there were only two deaths in ten cases, a mortality rate of 66 and 20 per cent, respectively. A similar difference was found in all the other groups except one. This greater mortality rate is, without doubt, caused on the one hand by the delay among the colored people in bringing the child's condition to the attention of a physician for diagnosis and on the other hand by the delay of the physician in making a correct diagnosis (table 8).

This study, like similar ones, has again brought out the fact that with children there is a very high mortality rate from acute surgical conditions within the abdomen, and that the earlier the condition is relieved by operation the better is the chance of saving the child's life.

Obviously, the utmost precautions must be taken to make an early and correct diagnosis of every acute condition within the abdomen, for should a surgical condition exist, the child's life is invariably at stake.

# ULCERS DUE TO VARICOSE VEINS AND LYMPHATIC BLOCKAGE

A NEW PRINCIPLE IN TREATMENT \*

HUGH H. TROUT, M.D.

ROANOKE, VA.

Before attempting to describe my conception of the principles underlying successful treatment in cases of ulcers due to varicose veins and lymphatic blockage, it is imperative to define more specifically the exact condition to be considered. Perhaps this can be done best by briefly mentioning the diseases to which I do not refer. It is not the small ulcer frequently found associated with varicose veins that has existed for only a short time, though such ulcers usually require more extensive operations than those commonly employed. It is certainly not the "trophic" ulcer, though sometimes, in these cases, a differential diagnosis is difficult and uncertain. It is not the syphilitic ulcer, although it is well to remember that patients with "leg ulcers" can have positive reactions to the Wassermann and Kahn tests and yet the ulcers apparently not be connected with syphilis. In such cases, of course, no operation should be done until after syphilitic treatment has been completed.

The type of ulcer to which I do refer is that one which all physicians remember dressing from month to month and often from year to year, without any marked success in the healing or diminution in the odor. Most of the modifications of Unna's pastes and adhesive straps have been used; some of the varicose veins have been removed with an insufficient amount of tissue under and around the ulcer; but, in spite of cherishing the hopes of an ultimate cure, most of these patients have returned only slightly, if at all, improved.

This state of affairs is best illustrated by the fact that in the twenty-seven cases on which this report is largely based, only two patients have not had previous operations. One patient in the series had nineteen operations, including all different kinds of skin grafts.

About twenty years ago, one fact became clear to me concerning this class of patients; namely, that the visiting surgeons, the resident surgeon, and often the interns did not want to be "bothered" with these disagreeable dressings, and, therefore, that the patients were not receiving the best possible consideration from the men in whom rested their best hope of relief.

In August, 1917, one of these unfortunate patients, who had had three separate and unsuccessful operations performed by surgeons in

---

\* Submitted for publication, Jan. 5, 1929.

various parts of America, came to me insisting on an amputation for relief from the pain and the odor. After much persuasion and following some then unjustified promises, she consented to allow me to try the principle, which I believe is essential to successful treatment in this condition. As the patient has remained well for eleven years, and there has been but one failure in the other twenty-six cases, the presentation of this subject would appear justifiable.

In this case, in which the operation was not successful, I was able to heal the ulcer and greatly improve the edema of the patient's leg, but, unfortunately, an epithelioma developed at the site of the skin grafts (pinch grafts). Since the patient would not allow radium to be used, he drifted out of my observation, and died. I was unable to find out the cause of his death, but was informed that the malignant condition had become extensive a few months before death. Sections of this epithelioma were definite, and I believe that the "sore" on his leg, after the patient was no longer under my observation, was a continuation of the malignant condition and not a recurrence of the ulcer. Of this, however, I am not certain. As this case is in the series, it should be included here, in spite of any views that I might have concerning the etiology of the epithelioma in the graft.

By "success" I do not mean to imply that the leg has become normal or that it is as good as the opposite and unaffected leg. However, these patients have been relieved from pain; the ulcers have completely healed; the swelling of the leg has been greatly reduced, and they have returned to their various occupations, without any marked degree of physical discomfort or the necessity of wearing an elastic stocking or applying Unna's paste legging.

These cases of ulcers have many points that are fairly constant. In most of the patients the varicose veins have been removed; all of them have swelling of the feet and legs below and around the ulcer. All the ulcers "weep" a thin serous, odiferous, pale yellow fluid, which irritates the surrounding skin and sometimes nauseates the attending physician.

The ulcers usually start on the inner and lower side of the leg, frequently spread until they become the well known "saddle shaped" and, occasionally, encircle the leg. Associated with these ulcers are always edema and swelling, which are naturally more marked after prolonged dependent positions.

It is, perhaps, trite and certainly always puerile to call attention to the necessity of thoroughly considering the causes of a disease before contemplating the principles underlying its cure. However, with these ulcers, I am sure there has not been sufficient consideration given to the etiology, otherwise, the usual accorded treatment would have been different. The generally accepted view, of course, is that the whole

process is due to damaged varicose veins with subsequent trauma and infection. Until recently no consideration has been given to the lymphatic system, either as a causative factor or as to its value in applying curative measures. It is in a proper valuation of the rôle played by the lymphatic system, I believe, that a distinct advance in the care of these chronic ulcers is to be found. However, before further considering the association of the lymphatics with the failure to cure such a large percentage of the chronic ulcers, by commonly accepted surgical procedures, it would be well to review briefly all the tissues involved.

#### ETIOLOGY OF ULCERS

*Varicose Veins.*—Homans, in 1916<sup>1</sup> and again in 1917,<sup>2</sup> presented the subject of varicose veins and ulcers in a most lucid manner and, to those who are interested in this subject, a careful perusal of both of his articles will be helpful in bringing every one to look at this complex problem from somewhat the same angle. He classified varicose veins according to their etiology into two groups: (1) those following mechanical forces due to occupations which require tension on the abdominal muscles, or prolonged standing on the feet, without exercise to assist in the return flow of venous blood up the leg by the muscles helping the veins push the blood from one valve to the one higher; (2) those due to infection such as phlebitis, "milk leg," etc.

A clear differentiation should be made between these two groups, for, with the cases of varicose veins following phlebitis, more careful attention should be paid to preventing the infection from involving the lymphatics. Infection is sooner or later superimposed on varicose veins due to mechanical causes, but the lymphatics are necessarily invaded by infection earlier when there is a primary phlebitis present.

It is possible that the day is not far distant when surgeons will be exercising segments of inflamed veins in postoperative and typhoid phlebitis, or "milk leg" following labor, etc. Such practice would hasten the period of convalescence, and also prevent infection from involving the lymphatics, which, as a rule, follows the course of the veins. Such practice would also tend to prevent the formation of future ulcers. For a "working basis," Homans also divided varicose veins into two other groups: (1) the simple surface varix, and (2) the surface varix complicated by varicosity of the perforating veins.

In order to differentiate properly these two classes, certain tests have been formulated, and it might not be out of place to recall them briefly. Not only do these tests help one in classifying the types of

2. Homans, J.: *The Etiology and Treatment of Varicose Ulcers of the Leg*, Surg. Gynec. Obst. **24**:300 (March) 1917.

varicose veins, but they also make one certain that varicose veins exist and that one is not dealing with a dilated and prominent vein associated with a diabetic, "trophic" or syphilitic ulcer. It is possible, though rare, to find calcification of the walls of varicose veins in patients who do not have arteriosclerosis. This process is probably a result of nature's attempt to prevent rupture of the wall of the vessel.

Tests for Classifying Veins: The three tests are as follows:

1. Trendelenburg's test is simple to apply. Have the patient lie on his back, raise the leg higher than the heart, then suddenly lower the leg below the level of the heart. The veins will fill out rapidly. If the walls of the veins are thickened, the impulse of the column of blood, unimpeded by the impaired valves, can be felt.

2. The "constriction" test is employed to ascertain whether or not the valves in the intercommunicating or "perforating" veins are functioning correctly. In this test, the leg is raised high enough to allow all the blood to run out and the walls of the veins to collapse. At this juncture, a constriction bandage (I have found the bandage of a blood pressure apparatus most useful) is placed around the thigh just tight enough to prevent the return of the blood through the surface veins. If the valves in the "perforating" veins are working, these prevent the blood from filling up the surface veins except in the normal manner. Such a process requires about one minute. On the other hand, if the valves in the "perforating" veins are not working properly, then the surface veins fill in from ten to thirty seconds, depending on how many of the valves in the "perforating" veins are not functioning.

3. The last test is one employed to demonstrate the patency of the deep femoral vein. The leg is allowed to hang down until the veins are distended, the constricting bandage is applied just tight enough to block the blood from going toward the heart through the surface veins. At this point, the leg is quickly lifted, and if the veins are collapsed in less than thirty seconds, then the patency of the deep veins is assured. Theoretically, this test sounds important, for were the deep veins completely obstructed and the superficial veins removed, gangrene might develop as a result of a blockage of the venous return. However, apparently a complete blockage of the deep veins does not occur, and I am unable to find in the literature any mention of such a surgical catastrophe. If there is ever a complete blockage of the femoral vein, it is more than likely that the rapid formation of a collateral venous system would prevent gangrene.

In many cases associated with edema and in abnormally fat people, these tests are of little value, for the veins cannot be seen and often cannot be felt. It is in such cases that a careful history, properly interpreted, is of paramount value in deciding on the best operative procedure.

Methods of Treatment: Varicose veins should be cured early and before secondary changes, such as infection, ulcers, lymphangitis, etc., have developed. At the start the condition can be corrected fairly easily by proper surgical measures. It is, in these cases that the comprehensive contribution of Dr. Homans has been of such great value. He called attention to the importance of correctly understanding the structure and function of the "perforating" veins which connect the superficial veins with the deep veins. It should be recalled that the valves in these "perforating" veins are so arranged as to allow the blood to go only from the superficial veins toward the deep veins. If these valves cease to function, there will naturally be a leakage of venous blood back into the soft tissues, with the consequent formation of a "stasis" ulcer, or the development of a varix. In accepting this state of affairs to be a fact, one must see the apparent necessity for ligating the "perforating" veins. Particularly is this true if the "constriction" test has demonstrated the valves in these veins to be defective.

Treatment for varicose veins by injection of various solutions has no appeal to my surgical instincts, for I cannot rid my mind of the fear of washing off emboli from some possible thrombus, in spite of the fact that the literature does not report such occurrences. It has been suggested to tie off the saphenous vein just before it enters the femoral vein and then to inject, and, in this way, to lessen the aforementioned possibility. If one is going to resort to surgical measures, one should employ surgical principles and not combine operation with "blind" procedures.

Unquestionably, many patients with varicose veins have been cured by the injection methods, but this procedure is not without its dangers. While no cases of death from emboli have been reported, still the literature contains the report of deaths from an apparently latent infection, which has been "stirred up" by the intravenous and perivascular infections. Most advocates of the injection methods warn against the possibility of injecting the solutions into the tissues around the veins on account of the subsequent formation of abscesses, etc., from tissue necrosis. Therefore, the method is not as easy as it might at first appear to be. In most of these large ulcers, it is impossible (due largely to the great amount of swelling present) either to see or to feel the veins. In such cases no injections should be attempted. I have seen four cases of ulcers of the leg in which the injection method had been employed: one of the patients did not have the ulcer until after injection into the vein, and there had been no improvement in the condition of the ulcer in the other three. However, I have seen personally many patients with varicose veins who have been either cured or markedly benefited by the injection method. When the varicose veins are definitely due to mechanical causes, intravenous injections might be a valuable addition

to the treatment; but when they are due to infection, the principle is unsound surgically and hazardous from a practical point of view. It is also next to impossible to estimate whether a latent infection in the vein is present or not.

As will be shown later in this article, the obstruction of the lymph channels plays an important rôle in the causation of ulcers, and the chemical irritation, with subsequent fibrosis on which the success of the injection method depends, serves to increase the chances of a lymphatic blockage, and, thereby, tends, possibly, to produce future ulcers. I have had no first hand experience with the method, but have seen a few patients treated elsewhere. I am not impressed with the advisability of forsaking sound surgical principles and substituting a method having theoretically an immediate danger of emboli as well as causing an almost certain injury to the lymphatic drainage with the future development of an ulcer.

No one operation is applicable to all types of varicose veins, but there is one procedure, which should never be omitted in any case, and, that is, the tying off, first, of the saphenous vein close to its entrance to the femoral. If possible, the vein should be removed from the thigh to a point below the knee. It is best to do this first before any form of attack is made on the veins in the leg. Numerous operations have been reported, such as: the ligation operations of Trendelenburg<sup>3</sup> and Schede,<sup>4</sup> the wide dissections of Madelung,<sup>5</sup> the spiral incision of Rindfleisch<sup>6</sup> and the "stripping" operation of Mayo<sup>7</sup> with many modifications—sufficient, in fact, to demonstrate that no one operation has been satisfactory for all classes of cases. The one selected should be applicable to each particular case according to the distribution and character of the veins, as well as the general physical condition of the patient.

*Arteries and Veins.*—After having studied the veins, one's attention naturally turns to the valuation of the rôle taken by the arteries and nerves. These are considered together, largely because of the intimate relation existing between the arteries and the sympathetic nerves. Naturally, in this connection one turns to the pioneer work of René

Leriche<sup>8</sup> and his co-workers. It is logical to presume that the infection, etc., which starts in the veins should ultimately involve the arteries, either by direct extension of the infection or by the increased resistance to the onward progress of the blood, causing a hypertrophy of the arterial wall. Evidently, Leriche<sup>8</sup> felt that by doing the periarterial sympathectomy he was able to overcome whatever handicaps might have been placed on the arteries by the formation of connective tissue around these ulcers. In fact, he stated:

The ulcer is consecutive to a dermo-epidermic necrosis springing from an arterial ischaemia, sometimes spasmodic, which creates a positive loss of substance always much greater than the apparent ulceration. The ulcer is incurable because the bad local circulatory conditions lead to an imperfect nutrition of the soft parts where the viability of the tissues is always mediocre.

In November, 1916, Leriche with his associate R. Fontaine<sup>9</sup> reported results in sterilization of infected wounds and ulcers by periarterial sympathectomy. Briefly, they stated three observations:

1. A chronic ulceration "is always infected to infinity by a large variety of microbial species." As the bacteria are found deep in the tissues, external medication is of no avail.

2. Soon after sympathectomy, the appearance of the ulcer changes.

3. From the fifth to the thirteenth day the wound is "practically and bacteriologically sterile." They ascribed this sterilization of the wound to the "afflux of leucocytes to the level of the ulcer." After making the ulcer sterile, they believe in replacing the lost skin by means of grafts, and prefer the Davis graft. They found that this sterilization of the ulcer is of comparatively short duration, it is, therefore, necessary to place the graft on the surface before reinfection takes place. They found the most favorable moment to be between the seventh and twelfth day after periarterial sympathectomy. Leriche, in speaking of varicose ulcers, made this final statement: "I make it a habit at the time of the sympathectomy to add to it a saphenectomy after the manner of Babcock." This is but another illustration of how, when one becomes enthusiastic concerning some particular point, one is apt to attach to it undue importance.

Knowing these views of Leriche, I decided to try periarterial sympathectomies in preparation for radical operation in two of these cases of extensive varicose ulcers. I regret that my results were not conclusive, for I could not see any more change in the ulcers on which

9. Leriche, R., and Fontaine, R.: The Sterilization of Infected Wounds and Chronic Ulcerations by Periarterial Sympathectomy. *Ann. Surg.* 84:625 (Nov.) 1926.

I had done a periarterial sympathectomy than I thought I had observed in somewhat similar cases of ulcers in which treatment consisted of rest and elevation of the leg. In these two patients, I did not obtain sterilization of the wound. With rest and elevation of the leg, there is lessened subcutaneous venous stasis and as a result decreased bacterial invasion. In these two patients, the prompt cessation of pain within twenty-four hours after the periarterial sympathectomies was striking. There was far more and quicker relief than is usually seen following rest and other methods employed in the preparation of patients for any operation for varicose ulcers. However, two cases are not sufficient material on which to make proper deductions, and, certainly, Leriche's reputation and surgical logic is such that his method deserves a much more extended observation by numerous surgeons.

It is possible that the combination of the lumbar sympathectomy or sacrosympathectomy with the periarterial sympathectomy might prove more satisfactory than the periarterial sympathectomy by itself. Such an operation is as extensive as the radical operation for varicose ulcer, which, when properly performed, gives definite and gratifying results.

Recently there have been numerous reports of the injection of alcohol into the nerves close to the ulcer for relief from pain. This, at best, is only a palliative measure and has no practical application in the preparation of the patient for operation, for pain is effectively relieved with rest and elevation of the leg. I cannot help but feel also that such injections produce fibrous tissue; thereby the lymphatic blockage is increased, and the treatment may prove distinctly harmful. However, physicians are just beginning to learn something about the surgical treatment of the nervous system and should withhold all hasty judgment.

It is interesting to recall that in 1851 Carnochan (quoted by Matas) ligated the main artery of the limb with the "view of restricting the circulation and, thereby, diminishing the tendency to lymph dropsy and stasis." No benefit resulted from this procedure.

It has been clearly demonstrated that the pigmentation of the skin seen before the ulcer forms is due to subcutaneous venous stagnation and the consequent failure of the venous and lymphatic systems to remove certain of the blood pigments. After the ulcer forms, the pigmentation usually continues to exist for several inches around the ulcer. With the skin in such a condition, the slightest trauma results in an abrasion on which infection is superimposed, and at such a site an ulcer quickly develops. The protective invasion of round cells is soon replaced by fibrous infiltration. Following this, blockage of the arterial supply, as well as of the venous and lymphatic return, occurs. If the infection is virulent, naturally necrosis of skin which sometimes involves extensive areas soon follows. To add discomfort, there is poured out on the skin a thin, watery, yellow fluid with a most disagreeable

odor. This excretion further irritates the already devitalized skin. It is more than likely that some of this excretion is lymph. To a less degree the same processes attack the subcutaneous fat, the fascia, the muscles, the periosteum, and, in severe cases, the tibia. In this series, there have been only two cases extensive enough to cause osteitis of the tibia. In both of these cases, there was the history of the "shedding" of superficial sequestrums. In fourteen other cases, not only was the periosteum involved, but there was also eburnation of the tibia to such an extent as to suggest strongly that the infection had extended to the bone.

With this extensive infection, the usual fibrous tissue replacement occurs, and, as years pass, this layer often becomes almost like leather. This layer of fibrous tissue sometimes contains areas of calcification. At this stage of the development, I believe two important factors are usually overlooked in the surgical treatment. The first is the one to which Dr. Homans has called attention, e.g., the "perforating" veins. The second is the lymphatics, which I shall now consider.

If the edema usually associated with these large ulcers and always present in the recurrent cases is due to a lymphatic blockage it is self-evident that measures must be instituted to overcome this condition, before any rational hope of a permanent cure can be entertained.

*The Lymphatics.*—Matas<sup>10</sup> called attention to the fact that simple mechanical edema is incapable of exciting proliferation of the connective tissue. He further stated that Unna, Darier, Le Dantec, Sir Patrick Manson and others have demonstrated that the blocking of the lymphatic channels with *Filariae* is not by itself sufficient to produce these connective tissue changes, but he thought that repeated attacks of streptococcal infection superimposed on the existing lymphatic block is necessary to cause the conditions found in the subcutaneous tissue and skin. A history of repeated attacks of "erysipelas" is associated with cases of "ulcer." While such attacks are not superimposed on a lymphatic blockage produced by *Filariae*, these streptococcal infections are grafted on a lymphatic blockage due to lymph coagulation and pressure from fibrous infiltration. Such being the situation, one occasionally sees an "elephantoid state" associated with these ulcers. Gesser, with Dr. Matas, reported one such case in 1913.

In his operation for elephantiasis, Kondoleon suggested a possible means of meeting this surgical dilemma.

Before accepting either the theory of the lymphatic block or Kondoleon's hypothesis of establishing communication between the superficial

---

10. Matas, Rudolph: The Surgical Treatment of Elephantiasis and Elephantoid States Dependent upon Obstruction of the Lymphatic and Venous Channels, Am. J. Trop. Dis., 1913, vol. 1.

and the deep lymphatics to relieve edema, it would be well to consider the accuracy of these theories.

In 1913, Florence Sabin<sup>11</sup> described the origin and development of the lymphatic system. To those interested in the embryology of this subject, a perusal of her articles will prove both profitable and interesting. Speaking in general terms, the lymphatics of the leg might be said to follow the veins in their development and distribution. As in the veins, there is a superficial and a deep system of lymphatics, but there is no intercommunication except through the popliteal and inguinal lymph nodes.

It has been demonstrated by Sabin, MacCallum, Lewis and others that the lymphatic supply is a distinct system of endothelial-walled vessels, not related either to the serous cavities or to the connective tissue spaces with which it has been confused so long, for the lymphatics grow by "budding" at the tips of their capillaries.

My own belief is that any accurate knowledge of the distribution of the lymphatics in the leg is limited and much confused at the present time, but with the constantly improving methods of injecting the various dyes there will soon be more reliable information.

Opie<sup>12</sup> has determined the coagulation time of lymph to vary between ten and twenty minutes as compared with that of blood, which is between four and six minutes. He expressed the belief that a slow coagulation of the lymph is due to the "scant quantity of thrombokinase present." This, taken in consideration with the fact that lymph contains no blood platelets, which is well known are essential to the formation of thrombi, would seem to prove that the blockage of the lymphatic channels from the coagulation of lymph is a rare occurrence. Opie,<sup>12</sup> however, has further proved that lymph coagulates readily within two and one-half minutes if "serum obtained from the surface of the wound" be added to the lymph. In his conclusion he stated: "The slow coagulation of lymph is hastened by the addition of thrombokinase, and thrombosis within lymphatic channels occurs when thrombokinase is liberated by the tissues in the wall of the lymphatic necrosis of cells in contact with the lymph stream favors thrombosis within the lymphatic vessels by bringing thrombokinase into contact with the circulating lymph." Certainly, if "necrosis of cells" and serum are prerequisite for the rapid coagulation of lymph, both are found in abundance in an ulcer. If this be true, it is reasonable to assume that blockage of lymphatic channels by rapid coagulation of lymph is as apt to occur with ulcers of the leg

12. Opie, Eugene: *Thrombosis and Occlusion of Lymphatics*, J. M. Research, 1913-1914, vol. 24.

as with veins when occluded by the formation of thrombi. Not only is there the possibility of lymphatic blockage from within its channel, but the certainty of obstruction from without, by the formation of the fibrous infiltration formed following infections. The deep lymphatics are largely protected from these changes by the protecting layer of fascia.

Kondoleon,<sup>13</sup> in 1912, in his operation for the cure of elephantiasis, advocated the removal of a long strip of this fascia so as to allow the lymph, etc., to be removed by the deep lymphatics. It is interesting to note that a review of the literature discloses only 142 cases of the Kondoleon operation for elephantiasis nostras streptogenes. In these reports, all of the patients have been improved. Kondoleon<sup>14</sup> reported twenty of these cases, and concluded that the ultimate outcome of the whole is not as good as was anticipated from the great improvement at first. All his patients have been improved, and in none did the condition grow worse. There must be a few hundred such operations which have not been reported in the literature, for I personally know of but few clinics where one or more of the Kondoleon operations have not been done. Burke<sup>15</sup> reported twelve cases but did not give the etiology of any of them. As these cases were in Porto Rico, *Filariae* might have been present. His results were bad. Sistrunk<sup>16</sup> stated that there has been improvement in his series of 100 cases, though in some instances, he had to do three or four operations before obtaining a satisfactory result. His experience has also been somewhat similar to that of Kondoleon as regards the permanency of the improvement. Sistrunk, further, feels that a large factor in the improvement of these patients is to be found in the removal of the diseased tissue, in addition to the removal of the fascial barrier and the regeneration of the lymphatics.

Naturally, the next question to arise is: What proof is there of any regeneration of the lymphatics? Of course, the success of the Kondoleon operation in improving the cases of elephantiasis nostra streptogenes is some clinical proof, but, in addition to such testimony, there has been much interesting experimental work to show conclusively that lymphatics do regenerate. The beneficial results following the removal of the fascia might be due to having the superficial tissues drained by the deep

lymphatics. However, as one reviews the experiments of Halsted,<sup>17</sup> Coffin,<sup>18</sup> Evans,<sup>19</sup> Opie,<sup>12</sup> MacCallum,<sup>20</sup> Reichert,<sup>21</sup> Sabin<sup>11</sup> and others, one cannot help but be impressed with the possibility and also the rapidity with which collateral vessels form and lymphatic vessels regenerate.

In 1906, Coffin,<sup>18</sup> under the direction of MacCallum,<sup>20</sup> sewed a loop of intestine through the wound in the skin. He waited for about ten days for granulations to form, and then made injections into the normal lymphatics on the surface of the loop. Not only did these lymphatics fill, but the injected fluid penetrated a short distance into the granulation tissue. Serial sections of these granulations showed these "penetrations" to be newly formed lymph channels. Histologically, it was not difficult to differentiate these channels from blood vessels, but, to be sure no mistake was made, he injected other colors into the blood vessels. Microscopically, these sections showed "sprouts into the granulation tissue which resemble closely sprouting blood vessels." The lumen of the channel narrowed to a point where the injection stopped. Beyond this there was a continuation of the endothelial cells, and it is probable these were the forerunners of future lymphatic channels.

Coffin's conclusion is: "It is seen here as always that the lymphatic channels are perfectly sharply outlined independent structures completely formed of endothelial cells and standing in no more intimate relationship with the crevices of the connective tissue than do the capillary blood vessels."

Structurally, the lymphatic channels are so delicate that they are hard to recognize, but since the introduction of proper methods of injecting dyes into them, knowledge of their presence in various organs has greatly increased. Even as far back as 1908, Evans<sup>19</sup> demonstrated the formation of new lymphatics in a round cell sarcoma. These new lymphatics were found to be in direct connection with the preexisting lymphatics, and as early as 1863, Krause,<sup>22</sup> by making injections with colored fluid into the skin adjacent to tumors, demonstrated the continuation of true lymphatics into new growths. If new lymphatic channels can form in a new growth, it is reasonable to suppose that they

can develop in the normal tissue found below the fascia and, to a lesser degree, in the somewhat fibrosed structures between the skin and the fascia.

In 1926, however, Reichert<sup>21</sup> in a series of experiments on dogs clearly demonstrated the formation of new lymph channels through scar tissue. He also showed infection delayed which, if extensive, almost prevented the penetration of new lymph channels across the barrier of scar tissue. It is interesting to recall that Reichert, with the late Professor Halsted, was trying to find the cause of the swelling of the arm which sometimes follows extensive operations for carcinoma of the breast.

Reichert quoted Billroth as having said, in 1863, that lymphatics did not grow across scar tissue in the early stages. He further quoted Billroth as follows:

You see that the young cicatrix, on the seventh day, when it still consists almost exclusively of cells, has no lymphatic vessels; these cease immediately at the young cicatrix; they do not form in the cicatrix until the fibrillary connective tissue bundles form. The granulation tissue also has no lymphatic vessels; where the inflammatory new formation, where the primary cellular tissue forms, the lymph vessels are mostly closed, partly by fibrous coagulations, partly by new cell formations. These observations have also been confirmed quite recently by Losch of St. Petersburg by examination of the traumatically inflamed testicles.

Reichert, in his experiments on dogs, severed all structures in the leg down to and around the femoral artery and vein, even cutting around the periosteum, as well as removing the adventitia from the vessels. All tissue was reapproximated with silk sutures, and no infection resulted in his series of experiments. India ink was injected into that portion of the leg distal to the transverse section. It was found that lymphatics formed across the line of scar as early as in four days, if the structures were accurately approximated. The superficial lymphatics were the first to regenerate, but the deep channels were found crossing the scar as early as eight days. The edema of the leg reached its maximum about the second day and began to subside about the fourth day or just about the time when regeneration of the lymphatic and venous channels was developing across the scar. He further proved, by injecting granules of India ink into the lymph channels, thereby blocking them, that the edema reappeared in spite of the fact that the veins had been reestablished in the meantime. He even went so far as to demonstrate that ligating the femoral vein did not cause edema if ligation was done in these dogs "when the subsidence of the swelling has just been completed." He further extended his experiments to prove that the edema was due to lymphatic and not to venous blockage. Infection, in the region of the scar, greatly delayed the regeneration of lymphatics.

Eloesser,<sup>23</sup> experimenting on the ears of rabbits, found that the lymph channels ultimately form across a scar, extending down to the cartilage, but he estimated that it took about four months for them to regenerate. He also found inoculation with a strain of streptococci (produced in the laboratory of Dr. Gay at the University of California) delayed this regeneration even longer.

Matas,<sup>24</sup> in 1913, called attention to the fact that chronic edema and swelling caused by lymphatic blockage was not in itself sufficient to produce the fibromatous changes found in elephantiasis, but that such changes were dependent on repeated infections probably with various strains of streptococci. It may be that the hard, brownish swelling found associated with these ulcers is not an "elephantoid" process, but to one seeing these ulcers of many years' duration, the relationship is most suggestive. Certainly, the usual history of repeated infections ("erysipelas") has much to do with the condition of the skin and underlying tissues. Homans,<sup>2</sup> in referring to the recurrent swelling associated with one of his cases of ulcer, stated "The difficulty may quite possibly be with the lymphatics, and the condition may be one of elephantiasis."

Some years ago, believing that the streptococcus plays an important part in these ulcers, I made a few injections of the stock (polyvalent) vaccines without any appreciable results. I have not been successful in obtaining any cultures from the tissues remote to the ulcer with which to make an autogenous vaccine. Either in the ulcer, or close to the same, the bacterial flow is too abundant to make a satisfactory vaccine. It might be that by following the method of Burbank of New York, or by removing an inguinal gland and "grinding" up the same after the technic developed in Baer's department in the Johns Hopkins Hospital, it would be possible to obtain an autogenous vaccine that would be of value in preparing the leg for operation as well as of service in preventing reinfections after operations. I expect to try the method of Burbank on the next few patients and hope to have more definite information relative to Baer's technic so that I can employ this also. Such studies will be the basis of a later report.

*"Milk Leg": Phlegmasia Alba Dolens.*—The extensive "milk leg" which follows phlebitis of the femoral and iliac veins presents a more difficult surgical problem than do the varicose veins and ulcers which follow phlebitis of the great saphenous vein. Owing to the support given to the walls of the deep veins by the surrounding muscles and fascia, as well as the assistance rendered by muscular contraction, varicosity

---

23. Eloesser, Leo: Obstruction to the Lymph Channels by Scar, J. A. M. A. **81**:1867 (Dec. 1) 1923.

24. Matas, Rudolph: Surgical Treatment of Elephantiasis and "Elephantoid" States Dependent on Chronic Obstruction of the Lymphatic and Venous Channels, Am. J. Trop. Med., no. 1.

of deep veins must be limited, if it ever occurs. Phlebitis of the femoral and iliac veins is not uncommon and when it does occur, there usually follows the well known swelling of the leg and sometimes the thigh, which is often associated with numerous small ulcers. This is a different picture from that of the large ulcer usually found "riding" on one of the superficial veins following phlebitis of the great saphenous vein. Associated with phlebitis, a thrombus is frequently found. When this occurs in the superficial veins there usually follows a compensatory dilatation of the veins with stretching of their walls, a consequent leakage of the valves, with the formation of varicose veins. When the phlebitis, however, attacks the femoral or iliac veins, there is damming back of blood (owing to the decreased size of the lumen of the vein) on the superficial system with, sometimes, the formation of varicose veins of both the perforating and the superficial veins. More often, the leg and thigh become edematous, sometimes presenting small ulcers, and the dilated veins are not seen.

My belief is that the edema, etc., is due not only to the blockage of the venous system, but also to the obstruction of the return of lymph. The obstruction of the lymph is due to the blockage of the lymph channels and nodes by the fibrous tissue, which follows the infection. This class of cases is most difficult to handle and the solution is found not only in the attention given to the veins, but also to the lymphatics. In such cases I believe both the width and the length of the fascial strip removed should be greater than the amount of fascia removed, when the lymphatic block is confined to the superficial lymphatics. To establish a free path for the unhampered regeneration of the lymphatics, it is necessary to remove the strip of fascia higher than the edema, particularly is this true when the swelling is the result of involvement in the deep vessels and lymphatics. Of course, in these cases the strip of fascia is removed from both the inner and the outer sides. In one case in which the swelling extended well up on the thigh I obtained a gratifying result by removing, on the outer side, the fascial strip several inches above the crest of the ileum. The extent of fascia removed is dependent, as in the Kondoleon operation for elephantiasis, on the amount of swelling present.

Walther,<sup>25</sup> before the advent of the Kondoleon operation, implanted the ends of small rubber tubes under the fascia lata, and then the other ends terminated in the peritoneal cavity. He did this in eleven cases of elephantiasis, and obtained marked, but temporary, improvement in all cases. He further advocated that such tube drainage be tried in cases of extensive and high phlegmasia alba dolens where the signs indicated

---

25. Walther, C.: Bull. Acad. de méd., Paris 79:195, 1918. (Buried Drainage for Elephantiasis. No. 10 nonperforated rubber tube from under the fascia into the abdominal cavity; three cases, all successful.)

involvement of the iliac vessels. However, he did not report operating on a patient.

I do not mean to imply that the swelling usually associated with these extensive ulcers of long duration is an elephantiasis. However, I do state that if these ulcers are allowed to continue long enough, the surrounding tissue will assume an "elephantoid state," which clinically and histologically resembles elephantiasis nostra streptogenes. If this observation is correct, extensive removal of the fascia is indicated in such ulcers. In ulcers of not so long standing and of limited involvement, this principle should also be applied, but such a condition does not require as extensive removal of fascia. The fact that recurrences are frequent after removal of varicose veins and grafting the ulcers shows, to my mind, that sufficient lymphatic return has not been provided.

I readily admit that in my enthusiasm I have been led to apply the operation in a few cases in which less extensive measures would probably have sufficed. However, the principle of establishing a sufficient lymphatic return is, I am sure, correct.

#### METHOD OF OPERATION

Before any operative procedure is attempted on these ulcers, the patient should be in bed with the foot elevated until the edema has greatly subsided. Such a course will add to the ease of the operation and decrease the chances of stirring up an old latent infection. Sometimes it is necessary to wait for several weeks before operating, but, even in such an event, time is gained, because patients treated in this manner have a much shorter postoperative convalescence.

As a rule, most of these patients have already had the varicose veins removed; if not, the veins should receive the proper attention at the time the remainder of the operation is being done. There is no difficulty in doing this as the same incisions give proper exposure for any desired procedure. The extent of the operation depends on the amount of edema present, the duration of the trouble, the age of the patient and other factors. If the edema is limited to the leg, the fascial strips need not be removed in the thigh. The longer the duration of the ulcer and the more extensive the edema, the more imperative it is to remove larger strips of fascia. The operation advocated is not different from many others in that it should be modified to suit the case. The following is a description of the operation applicable to the most extensive cases.

Incisions are made through the skin on both the inner and the outer side of the thigh and the leg. If the ulcer is on the inner side of the leg, as it most frequently is, the inner incision is carried to, roughly, within 3 inches (7.62 cm.) of the ulcer. The fat is then undermined for about 2 inches (5.08 cm.) on each side, removing with it all possible varicose veins that might have been overlooked. It is important to ligate all "perforating" or intercommunicating veins. A strip of fascia about 2 or 3 inches wide is then removed, as is done in the Kondoleon operation. The sides from which the strip of fascia have been removed are sewed down to the muscle with interrupted sutures. The skin on the side opposite to the ulcer is now approximated with silk sutures. On the side of the leg on which the ulcer is located an estimate is made of the amount of skin required to cover the raw area

from which the ulcer will have been removed. This is done in order to make a "chain" tubal graft which will be transferred at the proper time. The method of making this chain graft is simpler to do than to describe.

Most of the fat either from the anterior or posterior edge of the incision is removed for a distance of about 2 inches (5.08 cm.). The posterior edge is usually on the inner side, the easier site, for this edge is more freely movable as it does not lay over the tibia. Two, three, four or five incisions (depending on the amount of skin required are made), each about 3 inches (7.62 cm.) long and about 2 inches (5.08 cm.) from and parallel to the original incision. The ends of these incisions should be about  $1\frac{1}{2}$  (3.81 cm.) to 2 inches (5.08 cm.) from each other, and the lower one should end about 3 inches from the edge of the ulcer. A series of 3 inch "tube" grafts are then made by rolling the edges together and sewing them accurately, with interrupted sutures, so as to leave as little scar as possible. After these short "tube" grafts are made, the skin is approximated by sewing the cut edges under the grafts, except at the points between the ends of the grafts. The spaces between the ends of the grafts form a series of pedicles, which are to be cut later. Even at the site of the pedicle, the graft is loosely shaped so

Fig. 1.—Stages in operation for ulcer of the leg: *A*, incision on the outer side of the thigh and leg; *B*, incision carried down to fascia (the same type of incision is made on inner side when the ulcer is extensive); *C*, strip of fascia partially removed and the cut edges of the remaining fascia sewed to the muscle; *D*, strip of fascia completely removed and the cut edges of the remaining fascia sewed to the muscle.

as to become part of the future long tube and is held in position by sutures placed tightly enough only to shape the graft.

It is perhaps needless to state that up to this time the ulcer has been carefully covered and the operative field protected from contamination. After the application of proper dressings, the ulcer is exposed and all fibrous tissue removed with the ulcer. I have found it advantageous to cover the ulcer with gauze and make the incision well away from the margin of the ulcer. The incision is carried down until normal tissue is found, and then the whole mass is removed by dissecting underneath the thick base. It is essential that all fibrous tissue be removed to prevent any future lymphatic block. Any "perforating" or intercommunicating veins found (and usually there are several present under the ulcer) are carefully ligated. The operative field is cleared again, draped with fresh towels, etc., gloves and gown changed and a clean set of instruments used. This is required because it is necessary to remove the fascia down to the raw surface at the site from which the ulcer has been dissected, and therefore an aseptic field is again essential.

Much, but apparently not enough, has been said about the necessity of removing tissue wide of the ulcer in every direction until somewhat healthy tissue is found. Over twenty years ago, while an assistant to Dr. J. M. T. Finney, I well recall his insistence on the wide removal of these ulcers, particularly as regards the "leather-like" base. This procedure, associated with the proper attention to the varicose veins, will cure a large percentage of these patients, but it will not relieve either the multiple ulcers or those of long duration with swollen, brawny skin. The reason for this is probably that a ring of fibromatosis is left around the site from which the ulcer has been removed. In such cases it is necessary to remove a strip of fascia with some diseased subcutaneous fat, etc., in order to secure free communication between the superficial and the deep lymphatics. On one's willingness to do this thoroughly often rests the success of the operation. It is usual to find that this wide dissection carries one down to the periosteum and sometimes through

Fig. 2.—Further stages in operation: *A* shows three parallel incisions posterior to the first incision; *B*, skin approximated under these "tube" grafts; *C*, one pedicle cut leaving one long and one short tube graft; *D*, all pedicles cut except at the top and bottom of long "tube graft"; *E*, upper pedicle severed, tube "graft" cut open and sewed in the bed from which the ulcer is removed; *F*, lower pedicle severed, graft cut open and the remainder of the ulcer bed covered.

the same. If it is necessary to expose the tibia, holes about  $\frac{1}{8}$  inch (3.17 mm.) in diameter should be bored through the bone and into the medullary cavity to allow future granulations to form through these openings. These holes should be about  $\frac{1}{2}$  inch (12.70 mm.) apart. It is surprising to see how rapidly the granulation appears through them. Of course, the necessity for boring the holes exists only in rare cases. It is, however, interesting to note that Lanz of Amsterdam (quoted by Matas<sup>30</sup>), in 1906, in trying to obtain "deep lymphatic derivation" in his operation for elephantiasis, trephined holes in the tibia and placed a "number of pediculated strips of the fascia lata" through the opening into the medullary canal. It is well known that holes bored through the outer plate of the cranium,

when the scalp has been removed, will allow granulations to grow through the openings and form the bed for future grafts. The raw area is dressed with perforated rubber, such as is used in protecting skin grafts.

From seven to ten days after the operation, depending on the appearance of the various "tube" grafts, the pedicle of one end of one "tube" graft should be cut about  $\frac{1}{4}$  inch (6.35 mm) each day until the graft is completely freed except at

Fig. 3—*A* shows "saddle" ulcer of the leg, the type requiring removal of fascia on both sides of the leg and thigh; *B* shows removal of fat and fascia on the inner side of the thigh and leg, the ulcer being covered with towels; *C*, removal of fat and fascia on the outer side of the thigh and leg, a towel again being used; *D*, step in which the ulcer is exposed and the incision covered, the fat and fascia being removed down to the ulcer; *E*, removal of ulcer with a margin wide enough to find nearly normal tissue; *F*, removal until nearly normal tissue is found, even in some cases through the periosteum of the tibia.

the top near the knee and at the bottom near the ankle. The cut pedicles are rolled and the edges sewed together so as to complete one long tube graft, which should be ample to cover the area from which the ulcer has been removed. It requires experience, as well as common sense, to know when and how rapidly to cut the pedicles; the same is true in releasing the ends of the long tube graft.

From seven to ten days after the operation, depending on the appearance of the various "tube" grafts, the pedicle of one end of one "tube" graft should be cut about  $\frac{1}{4}$  inch (6.35 mm.) each day

Fig. 4.—Continuation of operative step in removal of "saddle" ulcer: *A*, boring holes in tibia for future granulations; *B*, first step in making a connected series of "tube" grafts, showing three pieces of gauze lifting up three tube grafts, each connected by an intervening pedicle; *C*, one pedicle has been cut leasing one long "tube" graft connected by an intervening pedicle, to lower and shorter "tube" graft; *D*, all pedicles except the lower one have been cut and the upper end of the "tube" graft split and sewed over granulations covering about half of the old ulcer; *E*, the remaining half of the graft is now covered and the site from which the ulcer has been removed completely covered with total thickness skin graft.

until the graft is completely freed except at the top near the knee and at the bottom near the ankle. The cut pedicles are rolled and the edges sewed together so as to complete one long tube graft, which should

be ample to cover the area from which the ulcer has been removed. It requires experience, as well as common sense, to know when and how rapidly to cut the pedicles; the same is true in releasing the ends of the long tube graft.

When ready for the graft, a Kelly clamp is applied to the upper pedicle and left on for ten minutes. The clamp is closed to the first serration of the lock. The next day the same procedure is carried out and the clamp closed to the second serration of the lock. This testing is continued until the surgeon can feel sure that the lower pedicle will take care of the circulation of the entire graft. After the top pedicle is severed, the graft is split for the proper length in its long diameter, turned down and sewed to the sides of the raw surfaces from which the ulcer has been removed. As soon as this is well healed, the lower end of the tube graft is cut and the graft split so as to be flattened out and cover the remainder of the raw surface.

It has been my experience that the total thickness graft is more satisfactory than the "pin," or Davis, graft. However, for various reasons, if one is not able to obtain the total thickness graft, the "pin" graft is easily and successfully applied. It is interesting to note that if there is any "break" or recurrence of the ulcer, it does not occur in the graft, but in the margin where the epithelium comes out from the periphery. In fact, I have used the total thickness graft only in eight cases, the rest has been "pin" and Thiersch grafts. In four cases I have successfully employed large Thiersch grafts at the time of primary operation. It is usually necessary to allow the granulations to come from around the edges and up through the holes in the tibia before the surface is ready to receive the "pin" grafts.

After the grafts have "taken," it is important to see that the patient does not put the leg in a dependent posture until the proper time. It is best to let these patients start by hanging the leg down for about an hour or until a faint cyanosis occurs. This method of "testing" the leg allows the patient slowly to resume his duties. However, I believe it wise in all these cases for the patient to use an elastic bandage or Unna's paste stocking for at least six months after leaving the hospital.

#### SUMMARY

1. The operation advocated is applicable only to extensive or multiple ulcers, particularly to those of many years' duration and associated with much swelling. (In some of these cases numerous unsuccessful operations on varicose veins have been performed.)

2. The operation advocated is simply the application of the method presented by Kondoleon in his treatment for elephantiasis plus wide excision of the ulcer and the employment of total thickness skin grafts when possible. Many of these cases are both clinically and histologically somewhat similar to elephantiasis.

3. The clinical results reported indicate that there is either a regeneration of the lymph channels or a rapid establishment of a collateral lymphatic circulation. The experimental work of others confirms both views.

4. In addition to the operation advocated, it is necessary to be certain that proper attention has been given the venous system,

especially the ligation of the "perforating" veins. The three tests for determining the condition of the veins are all useful and should be employed when possible.

5. In two cases in which periarterial sympathectomy was tried, the results did not seem to verify the claims of the healing or the sterilization of the ulcer.

6. Injection of alcohol close to the ulcer for relief from pain or the intravenous administration of various solutions for the cure of varicose veins associated with ulcers appears to me surgically unsound.

7. Much interesting and instructive work has been inspired by the late Dr. W. S. Halsted and his co-workers concerning the origin, development, function and regeneration of the lymphatic system. Much of this work was done while trying to ascertain the cause of the swelling of the arm which sometimes follows operations for cancer of the breast.

8. There are only 142 cases of the Kondoleon operation for streptogenic elephantiasis reported in the literature, though there must have been many hundreds of others not reported.

9. The polyvalent vaccine of streptococci has not proved of any benefit in the condition discussed either for cure or for prevention of recurrences. It is possible that the technic of either Burbank or Baer might prove of aid in obtaining an effective autogenous vaccine.

10. The cure of phlegmasia alba dolens ("milk leg"), either with or without ulcers, requires a more extensive removal of fascia.

11. This report is based on twenty-seven cases, in twenty-six of which the ulcer was cured and there was marked relief of pain and edema. One patient died from an epithelioma, forming in the grafted area. This patient refused the employment of radium. All the rest of the patients have returned to their former occupations.

# RADIOSENSITIVE INTRA-ORAL TUMORS

## A CLINICAL STUDY \*

MAX CUTLER, M.D.

Clinical Fellow in the Memorial Hospital

NEW YORK

It is the purpose of this study to call attention to a group of malignant epithelial tumors which may be separated from the general class of epidermoid carcinomas because they present peculiar clinical manifestations, a specific histologic structure and a remarkable susceptibility to radiation. A notable variation in the natural history of certain intra-oral tumors has been previously observed. Thus, Ewing<sup>1</sup> stated that within the group of epidermoid carcinomas, particularly of the tonsil, base of the tongue, nasopharynx and larynx, cases occur which show a high degree of malignancy and run an unusually rapid course. The peculiar histologic structure of these tumors, notably the absence of squamous features and the presence of transitional epithelial characters has also been noted. In 1921, Regaud recognized the peculiar microscopic changes and radiosensitivity of certain tonsillar and nasopharyngeal tumors. He was impressed with a close and constant relation between the epithelial and lymphoid elements and, on account of the resemblance of this structure to normal lympho-epithelial tissue, applied to them the term "Lympho-epitheliome." The case presenting these unusual histologic features was reported by Reverchon and Coutard<sup>2</sup> and concerned a tumor of the hypopharynx which showed a marked response to radiation. At about the same time (1921), Schmincke<sup>3</sup> reported several cases of carcinoma of the tonsil and nasopharynx which displayed an unusual susceptibility to radiation and a structure similar to that described by Regaud; these he also designated as "Lympho-epitheliome."

In 1923, Mlle. Derigs<sup>4</sup> reported a case of lympho-epithelioma of the pharynx with metastases to the vertebral column and abdominal viscera, in which the structure of the metastatic tumors was described as being composed of undifferentiated cells infiltrated by lymphocytes and resembling the original tumor.

That the peculiar clinical manifestations of these tumors were previously recognized is shown in a publication by New<sup>5</sup> in 1921, in which the syndrome of malignant tumors of the nasopharynx is described. He noted the difficulty of detecting the primary lesion, pointed out the frequency with which the metastases in the cervical nodes were erroneously regarded as the primary tumor and the necessity for a careful search elsewhere for a small and hidden primary focus.

The peculiar clinical manifestations of tumors of the nasopharynx were also described in 1923 by Crowe and Baylor<sup>6</sup> who reported a series of cases and demonstrated by means of excellent illustrations their special histologic structure. These authors pointed out the structural resemblance between these tumors and the sarcomas and emphasized the difficulty in the histologic differentiation of the two processes.

In 1925, Quick and Cutler,<sup>7</sup> studying changes in tissues due to irradiation, reported their observations on a series of metastatic tumors in cervical lymph nodes. It was noted that certain epidermoid carcinomas, especially of the tonsil, base of the tongue and nasopharynx, presented a specific histologic structure, displayed a marked susceptibility to radiation and pursued an unusual clinical course. The term transitional cell epidermoid carcinoma was applied to these tumors. This report was followed by a further clinical and pathologic study of twenty cases observed over a period of three years, with several observations<sup>8</sup> obtained at autopsy.

Jovin,<sup>9</sup> in 1926, reported a series of cases from the Radium Institute of Paris and described the clinical, pathologic and radiotherapeutic features of the disease. This author expressed the belief that these

tumors arise from the lympho-epithelium occurring normally in these locations. The high degree of malignancy, rapid and widespread metastases and marked susceptibility to radiation are emphasized as the essential clinical features of the disease.

#### HISTOLOGIC STRUCTURE

The microscopic structure of the group of tumors which I have described presents the following two fairly distinct histologic types: (a) Lympho-epitheliomas, forming a small proportion of the cases, are recognized by the syncytial masses and rich infiltration with lymphocytes. (b) Transitional cell carcinomas, the more common variety, present the features of anaplastic epidermoid carcinoma; in these, the epithelial characters are distinct and lymphocytes are absent.

It remains for further investigation to determine whether any clinical differences can be demonstrated between these two histologic varieties. In a certain small proportion of cases, the histologic structure does not permit a differential diagnosis between lympho-epithelioma, transitional cell carcinoma and lymphosarcoma, since the cells are loose and broken up as in lymphosarcoma. In these cases, the diagnosis may sometimes be reached only after careful consideration of the clinical observations in conjunction with the microscopic picture. It is particularly to be noted that all these types are highly radiosensitive and can readily be distinguished from squamous carcinoma, both histologically and clinically.

*Lympho-Epithelioma.*—A small proportion of tumors of the tonsil and nasopharynx present a structure which coincides with those tumors described by Regaud and by Schmincke as "lympho-epithelioma." In these cases, the structure shows epithelial cells in wide sheets and cords growing diffusely and infiltrating the surrounding lymphoid tissue. The cells are large, pale and delicate with a thin cell membrane. The protoplasm is ill defined, has a trabeculated arrangement and often forms a true syncytium. The nuclei are large, clear and pale, and show marked variation in size. Nucleoli are prominent and mitoses abundant. In places, the lymphocytic infiltration is so thick that the tumor cells are hardly visible through the lymphoid structure. Occasionally, one sees larger cells in the reticulum, round or polyhedral, with hyperchromatic nucleus and sometimes multiple nuclei.

The structure in general strongly suggests primary endothelioma and is often difficult to distinguish from reticulum cell lymphosarcoma. The intimate association between the clear endothelial-like cells and the lymphoid tissue suggests an origin from lympho-epithelium as described by Jolly and forms the basis for the term lympho-epithelioma. This structure is relatively rare. In a review of 300 tumors of the base of the tongue, tonsil and nasopharynx, only nineteen, or 6.3 per cent, were found to fall into this group (Ewing).

*Transitional Cell Carcinoma.*—The structure to which this term has been applied shows mainly small round and polyhedral cells with relatively large hyperchromatic nuclei which occupy almost the entire cell. The cells vary markedly in size and staining intensity, and mitoses are abundant. The cells grow diffusely in cords and sheets and infiltrate the surrounding lymphoid tissue. The arrangement is sometimes plexiform. There is little intercellular connective tissue. Polymorphonuclear leukocytes, lymphocytes and plasma cells are numerous. The cells show marked loss of differentiation, and squamous characters are entirely lacking. These tumors sometimes reach a high grade of anaplasia, so that the growth is diffuse and the epithelial characters of the cells almost lost. This structure often approaches the appearance of lymphosarcoma so closely that a differentiation between the two processes may be difficult.

The metastatic tumor in the cervical lymph nodes usually has a structure similar to that of the primary tumor. Rarely, some traces of squamous characters are found, although more often the metastatic process tends to become more undifferentiated. Invasion of lymphatics and blood vessels in the primary tumor by groups of tumor cells is often encountered and accounts for the early involvement of the lymph node in these cases. Tumors presenting this structure are more common than lympho-epitheliomas and occur less frequently than squamous carcinomas. They comprise approximately 10 per cent of epitheliomas occurring in these regions.

The similarity in the histologic structure between these tumors and radiosensitive tumors in other locations is noteworthy. The esophagus is sometimes the seat of anaplastic epidermoid carcinomas presenting the structure, clinical course and radiosensitivity of transitional cell carcinoma. In a study of 200 cases of carcinoma of the cervix, it was found that 20 per cent were highly cellular anaplastic tumors presenting all the histologic features of this group.<sup>10</sup> In the clinical course and sensitivity to radiation, this type of carcinoma also simulates the intra-oral group. These observations lend support to the belief that in all these groups one is dealing with radiosensitive anaplastic epidermoid carcinomas which present a uniform and characteristic structure and are accompanied by a definite clinical course.

### HISTOGENESIS

Although the exact origin of these tumors is not definitely known, several possible sources suggest themselves. In this discussion, it is important to reemphasize the distinction between true lympho-

10. Healy, W. P., and Cutler, M.: Relation Between Structure and Prognosis in Cervical Carcinoma Under Radiation Treatment, *Am. J. Obst. & Gynec.* **16**:15, 1928.

epithelioma and transitional cell carcinoma, as there is considerable evidence in favor of the view that each variety may have its own source of origin. The view held by Regaud, Schmincke, Lacassagne and others

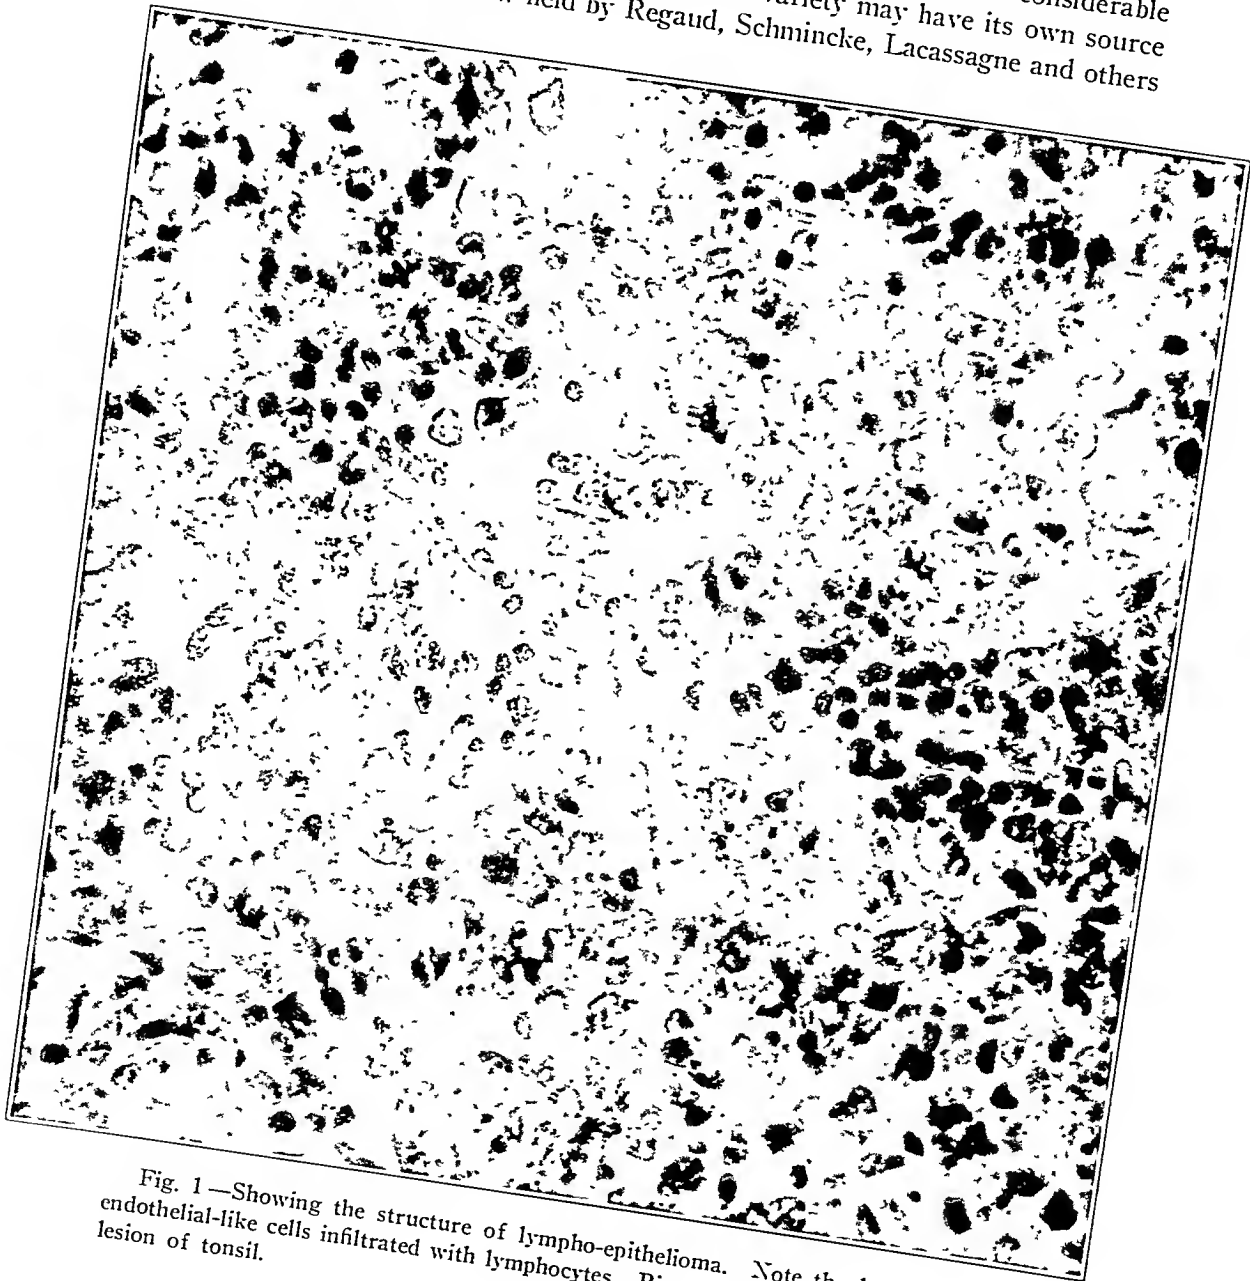

Fig. 1—Showing the structure of lympho-epithelioma. Note the large, clear endothelial-like cells infiltrated with lymphocytes. Biopsy specimen from ulcerated lesion of tonsil.

is that lympho-epitheliomas arise from squamous epithelial cells which are in close contact with and often infiltrated by lymphoid tissue to which the term "lympho-epithelium" was applied by Jolly. These authors are

of the opinion that the essential feature of the histologic structure of these cells is an intimate association of endodermal epithelium with lymphocytes. Evidence in favor of this view is found in the prevalence of tumors presenting this structure in locations in which lympho-epithelial tissue is described, namely, the tonsil, base of the tongue and

Fig 2—Lympho-epithelioma of superior nares showing large, clear, pale nuclei and prominent nucleoli. Note the thick infiltration with lymphocytes.

nasopharynx. On the other hand, it is pointed out by Delbet and others that the exact rôle of the lymphocytes in the histologic structure is not fully known.

Whereas it is possible that lympho-epitheliomas arise from a special tissue, it is altogether probable that anaplasia rather than a special cell

of origin accounts for the peculiar histologic features of transitional cell carcinoma. This view gains support in the fact that a relatively high proportion of tumors of the tonsil, base of the tongue, pharynx and larynx are distinctly squamous in character and also in the occasional

Fig 3—Showing the structure of transitional cell carcinoma. The tumor shows small, round and polyhedral cells with hyperchromatic nuclei growing in cords and sheets. Biopsy specimen from lesion of nasopharynx.

presence of highly undifferentiated cells in growths which are essentially squamous.

Since it is the essential purpose of this study to call attention to the clinical features and therapeutic aspects of this disease, it is not within

the scope of this paper to enter further into the details of their histogenesis. The complexity of this phase of the problem calls for special histologic investigations into the exact origin of these tumors, a point which for the present must be regarded as still unsettled.

Fig. 4.—High power view of figure 3. There are no definite squamous features. Note also the absence of lymphocytic infiltration.

#### PRIMARY LESION

The common locations of the primary tumor are the pharyngeal tonsil, lingual tonsil, base of the tongue and nasopharynx. The larynx and esophagus are not infrequently the seat of anaplastic and radiosensi-

tive tumors which may be classed in this group. The primary focus is usually small and frequently insignificant in its proportions. It presents, on inspection, a finely granular surface suggestive of erosion, rather than frank ulceration. In some instances, especially in the early

Fig 5—Necrotic tumor tissue in cervical lymph node, the seat of metastatic lympho-epithelioma after moderate external irradiation. Primary lesion in tonsil (fig 1).

stages of the disease, there have been neither erosion nor ulceration but rather the appearance of fixation of the mucous membrane over a mass beneath it. The lesion is usually flat and gives the impression of having

taken its origin in the deeper structures and then adhered to and eroded the mucous membrane from beneath. Sometimes, the lesion is diffuse, extending around the pharyngeal ring and involving the mucous membrane of the base of the tongue, tonsils and posterior pharynx with superficial ulceration and bilateral cervical adenopathy. In several cases, the primary lesion in the tonsil has consisted of a tumor, as large as a hen's egg, projecting across the midline and causing interference with breathing and swallowing.

#### CERVICAL ADENOPATHY

Early metastatic involvement of the cervical lymph nodes is one of the most constant and characteristic features of this disease. In only a few early cases has this been absent when the patient first came under observation. The cervical nodes, at first small, grow rapidly and soon form a bulky mass. The location varies somewhat but usually is in the middle and upper cervical regions beneath and in front of the sternomastoid muscle and reaching upward to the lower lobe of the ear. The consistency is perhaps firmer than that of lymphosarcoma but lacks the induration of squamous carcinoma. The tumor process has a greater tendency to remain encapsulated than does squamous carcinoma, remaining more or less freely movable except in the later stages. Perforation of the capsule is sometimes seen, but spontaneous ulceration has not been observed. The usual history accompanying these cases is that for six, eight or ten months a cervical mass has been noted; and in several cases the presence of a mass for as long as from one to three years has been established. An interesting and unusual feature of these tumors is the occasionally long period of quiescence of the cervical adenopathy. The stimulus to further activity usually has been some acute infection in the nose, mouth or throat. At first unilateral, the adenopathy soon extends and involves the opposite side of the neck. A bulky cervical adenopathy, however, may remain unilateral for many months. In the early stage of the disease, pain is nearly always absent; in the more advanced stages, the bulky mass begins to cause pressure symptoms. The pain is sharp, and is often referred to the ear, postauricular and occipitoparietal regions.

#### VISCERAL METASTASIS

Visceral metastasis is of frequent occurrence in this variety of tumor, in marked contrast to the extreme rarity of distant metastasis from intra-oral squamous carcinoma. The liver and retroperitoneal lymph nodes have been found to be the seat of bulky metastatic tumors from small primary intra-oral lesions. Metastasis to bone is reported by Jovin, who observed patients showing clinical and roentgenologic signs of metastasis to the vertebral column. On account of the absence of definite evidence at autopsy, however, the author leaves this question open to further

study. Through the courtesy of Dr. Scoville, it was my privilege recently to study specimens of a nasopharyngeal tumor showing the typical feature of lympho-epithelioma which produced metastases in the bones of the ankle and the elbow. Tissue taken from the metastatic deposits in the ankle showed the same histologic structure as the primary tumor. This observation is, therefore, in accord with the reports of Jovin and others in regard to this mode of dissemination.

That the disease may progress for long periods without visceral involvement is demonstrated by several cases in which the primary lesion and cervical adenopathy had been present from one to two years without clinical evidence of visceral metastasis. Further evidence of this is shown by the absence of visceral metastases in several autopsies on patients who succumbed to the disease from one to three years after the onset of symptoms. In one patient, acute intestinal obstruction developed as a result of pressure of a large mass of retroperitoneal lymph nodes on the splenic flexure of the colon. The other patient presented large multiple tumors in the liver and retroperitoneal nodes at autopsy.

Whereas the microscopic structure of the cervical node metastases is usually similar to that of the primary tumor, the structure in the visceral deposits often assumes more anaplastic features. In one case, the hepatic tumor presented an extremely cellular anaplastic structure strongly resembling lymphosarcoma, whereas the primary lesion showed the typical appearance of lympho-epithelioma. This phenomenon is known to occur in other tumors in which the metastatic process appears to have taken on an added growth potential and displayed a more undifferentiated and anaplastic structure.

#### CLINICAL COURSE

The clinical course of this group of tumors is as characteristic as the histologic structure and differs from that of other tumors in these locations. In my experience, more patients have sought advice regarding a mass in the neck than for intra-oral symptoms. The appearance of large cervical nodes, while the primary intra-oral tumor remains undetected, is one of the notable peculiarities of this disease. A careful search for the primary lesion may reveal a small hidden tumor in the base of the tongue, tonsil or nasopharynx. On the other hand, thorough search may fail to reveal the primary growth. It would seem that the logical explanation for this course of events is that the lesion being deep-seated and the tumor cells of a type which metastasize early, the cervical metastases appear and grow before the primary tumor reaches the surface and ulcerates. Ulceration, pain and bleeding may not occur until late in the disease. In the meantime, the clinical setting is dominated by the metastatic process, and the cervical adenopathy presents the picture of a primary disease of the lymph nodes. The failure to detect

the primary growth leads to various erroneous diagnoses, including branchiogenetic carcinoma, endothelioma, lymphosarcoma, tuberculous adenitis or simple chronic lymphadenitis. Soon afterward, the mucous membrane becomes ulcerated, and pain and bleeding direct attention to the primary focus.

Analysis of the clinical features of a series of twenty cases showed that thirteen patients had noted enlarged cervical nodes as the first sign of disease before any abnormality referable to the intra-oral region was detected. In five patients, thorough search failed to reveal a primary intra-oral lesion, and the disease progressed under various diagnoses of primary diseases of the lymph nodes.

The peculiar clinical course of this disease has been noted by other investigators. In a clinical study of carcinomas of the nasopharynx, Crowe and Baylor stated that the first sign of carcinoma in this region is often a painless and rapid increase in size of the deep cervical nodes at the angles of the jaw. In seventy-nine cases of carcinoma of the pharynx reported by New, fifty-one of the patients had enlarged cervical nodes. Eighteen of the fifty-one patients in whom the cervical nodes were involved had had operations on the neck without discovery of the primary tumor. A microscopic diagnosis of endothelioma of the lymph nodes had been made in three cases. My former impression that the course of the disease is always rapid and soon leads to fatal termination was based on the fact that most of the patients when first seen had been subjected to one or more incomplete operations. An opportunity to observe several cases in which the disease had been permitted to pursue an undisturbed course has demonstrated that the natural course may sometimes be extremely slow.

#### DIFFERENTIAL DIAGNOSIS

Lympho-epithelioma and transitional cell carcinoma must be differentiated from squamous carcinoma, lymphosarcoma, branchiogenetic carcinoma and endothelioma. Although typical cases may be recognized clinically, a differential diagnosis may be extremely difficult and possible only with the aid of a biopsy.

In its generalized secondary extensions and wide dissemination, as well as its prompt and rapid response to radiation, this disease simulates lymphosarcoma more nearly than it does the group of epidermoid carcinomas. Lymphosarcoma is more rapid in its course, tends to appear bilaterally in the early stages of the disease and soon produces constitutional symptoms. The response to radiation does not permit differentiation as the two tumor processes are about equally radiosensitive. Lymphosarcoma is often discovered after tonsillectomy.

Although typical lymphosarcoma and transitional cell carcinoma are readily distinguished microscopically, certain borderline structures are

extremely difficult to interpret, and a differential diagnosis based on structure alone may be impossible. In such cases, the clinical observations are of considerable help in the differentiation. Fortunately, an absolute distinction between the two conditions may not be important from a practical standpoint as the treatment is essentially similar in the two diseases.

Branchiogenetic carcinoma is distinguished by its histologic structure. It is nearly always squamous and consequently resistant to radiation. It differs, therefore, in this important respect from the markedly radiosensitive transitional cell carcinoma and lympho-epithelioma. This marked difference in response to radiation may be utilized practically in the differential diagnosis.

Primary endothelioma of lymph nodes may simulate transitional cell carcinoma in which the nodes are enlarged and the primary lesion is undetected. The disease is comparatively rare and commonly arises on the basis of a chronic granulomatous inflammation, especially tuberculosis. It may occur as a systemic involvement of many lymph nodes or as single or multiple tumors of cervical, axillary or other lymphatic chains. The history of an antecedent tuberculous infection, the lack of response to radiation and the persistent failure to find a primary intra-oral lesion are differential points in favor of endothelioma. Ewing stated that a diagnosis of primary endothelioma of the lymph nodes is hazardous and is to be made only by exclusion. Furthermore, it is important to recognize that endothelioma is rare, whereas secondary carcinoma is relatively common.

#### RESPONSE TO RADIATION-THERAPEUTIC TEST

The marked radiosensitivity of this group of tumors constitutes one of its most characteristic and important properties. It is this feature of the disease that first led to its discovery and recognition as an entity. Rapid regression and disappearance of the primary lesion and cervical adenopathy in response to relatively weak doses of radiation are reported by Regaud, Schmincke, Jovin, Jungling and others.

The mode of regression of this radiosensitive tumor process undoubtedly differs from that of the radioresistant tumors. Destruction of squamous cell carcinoma must occur through an intensive and almost caustic action of interstitial irradiation or by heavy external irradiation, whereas complete primary regression of radiosensitive transitional cell carcinoma or lympho-epithelioma may often be accomplished by means of external irradiation alone. The rapid regression of these tumors is associated with an equal tendency to rapid recurrence if the tumor process is not completely sterilized. The radiosensitivity of these tumors differentiates them sharply from the radioresistant squamous carcinomas and branchiogenetic carcinoma. These differences assume considerable

importance from a diagnostic standpoint, so that external irradiation may serve as a useful means of differentiation in the diagnosis of obscure cervical tumors.

#### TREATMENT

In a consideration of the method of choice in the treatment for this disease, it is important to emphasize the two properties of these tumors on which the principle of therapy is based: (1) their high degree of malignancy and (2) their marked susceptibility to radiation.

The extremely unfavorable results of surgical intervention in the treatment for highly cellular anaplastic tumors in any location is now becoming universally recognized. The hopeless prognosis of carcinoma of the tonsil under surgical treatment may be attributed largely to the highly malignant nature of the tumor process. The inaccessibility of the primary tumor adds further difficulty to surgical removal. Histologic observations have demonstrated the early tendency of these tumors to invade the lymphatics, a property which accounts for their early and extensive metastasis. Any method of treatment to be successful must be devoid of trauma in order to prevent dissemination of this extremely unstable cellular tumor.

The principles of irradiation in this disease are based on the marked susceptibility of these tumors to this agent. Because of their high degree of malignancy, local recurrence and metastasis invariably follow the primary regression, unless a complete sterilization of tumor cells can be accomplished. This may be affected either by x-rays or radium, or by the two agents combined. If complete sterilization of the tumor process can be accomplished by means of heavy external irradiation alone, this method is to be preferred. In some cases, it has been necessary to add further irradiation by the implantation of gold filtered emanation into the primary lesion. It is believed that the dosage should be the maximum amount of radiation which can be delivered to insure complete destruction of the tumor and still preserve the integrity of the tumor bed.

The ability to care completely for the primary lesion and metastatic cervical nodes by radiation has been demonstrated clinically and microscopically. The danger lies in the early dissemination of the disease to the viscera, so that whereas the primary lesion and cervical metastases have been cared for, the patient returns with bulky visceral metastases. For this there are several possible explanations: (1) failure completely to sterilize the primary lesion or cervical metastases; (2) dissemination of the disease by operative trauma, and (3) the presence of clinically undemonstrable visceral metastases when treatment is instituted. The highly anaplastic nature of the tumor and its high grade of potential malignancy favor the view that when the cervical nodes are

involved minute distant metastases are already present. On the other hand, it would seem that the disease may remain localized in the cervical nodes for some time. This is demonstrated by a number of cases in which a cure has been effected and is supported by evidence obtained at autopsies. Thorough and adequate irradiation in this stage of the disease offers considerable hope of complete sterilization of the tumor and cure of the patient.

TABLE 1.—*Nine Cases of Transitional Cell Carcinoma and Lympho-Epithelioma in which the Patients Have Been Well and Free of Disease More Than Three Years*

No	Sex	Age	Duration of Condition	Location	Nodes	Bopsy Primary Lesion	Microscopic Examination of Nodes
1	M	53	4 years	Tonsil	+	Transitional cell carcinoma	Invaded
2	F	44	9 months	Tonsil	+	Transitional cell carcinoma	Invaded
3	M	59	10 months	Base of tongue	+	Transitional cell carcinoma	Invaded
4	M	43	6 weeks	Base of tongue	+	Lympho-epithelioma	Invaded
5	M	56	2 years	Tonsil	+	Transitional cell carcinoma	Nodes not removed
6	M	40	2 months	Naso-pharynx	0	Transitional cell carcinoma	No nodes
7	M	44	6 months	Tonsil	+	Transitional cell carcinoma	Invaded
8	M	61	2 months	Larynx	+	Transitional cell carcinoma	Invaded
9	M	59	2 months	Larynx	+	Transitional cell carcinoma	Nodes not removed

Case	Treatment				Result Free of Disease
	X-Rays	Surface Radium	Base Tubes	Operation	
1	0	+	+	+	11 years
2	+	0	+	+	9 years
3	+	0	+	+	5 years
4	0	+	+	+	4 years
5	+	+	+	0	4 years
6	+	+	0	0	3 years
7	+	0	0	0	3 years
8	+	+	+	+	4 years
9	+	0	0	0	3 years

## RESULTS

It is not possible at this time to give in detail the total number of patients treated. This difficulty is due mainly to the fact that this condition has been recognized as a clinical and pathologic entity only within recent years. It has been possible, however, to select nine patients belonging to this group on whom treatment was begun more than three years ago, who are now well and apparently free from disease. It should be emphasized that this number of patients probably represents but a small percentage of the total number who have been treated. These cases are reported merely to relate the treatment which has been

employed in the patients who have responded well, and to demonstrate that the disease may be controlled by these methods in a small but definite proportion of cases.

Analysis of the important feature in the group of controlled cases shows that four were carcinomas of the tonsil, two of the base of the tongue, two of the larynx and one of the nasopharynx. Six of the patients had involved cervical nodes, confirmed microscopically, and two others had undoubted invasion of the cervical nodes clinically. In only one of the nine cases were the nodes free from disease. Two patients, one with an advanced carcinoma of the larynx and the other with an extensive carcinoma of the tonsil, were free from disease three years after the employment of external irradiation alone. Both had well marked involvement of cervical lymph nodes. One patient with a carcinoma of the nasopharynx without involvement of the nodes was well three years later, after surface irradiation alone. One patient with a carcinoma of the tonsil and extensive involvement of the cervical node was free from disease four years after combined external and interstitial irradiation. The other six patients were treated by combined external and interstitial irradiation and surgical removal of the cervical nodes.

#### SUMMARY AND CONCLUSIONS

1. Transitional cell carcinomas and lympho-epitheliomas comprise a group of malignant tumors commonly found in the tonsil, the base of the tongue and the nasopharynx and characterized by a peculiar clinical course, specific histologic structure and marked susceptibility to radiation.

2. Although the exact histogenesis of these tumors is not definitely known, it is suggested that each type may have its own source of origin as follows: (a) transitional cell carcinoma, from squamous epithelial cells which in their growth have become undifferentiated and assumed anaplastic features; (b) lympho-epithelioma, from a special tissue described as lympho-epithelium.

3. The clinical course is characterized by early metastasis to cervical lymph nodes so that the clinical picture is dominated by the metastatic process while the small deep-seated primary lesion remains for a time undetected.

4. The enlargement of the cervical nodes before the primary lesion ulcerates and produces symptoms often leads to erroneous diagnoses of primary disease of the lymph nodes (endothelioma, lymphosarcoma, branchiogenetic carcinoma and tuberculous adenitis). It is important, therefore, thoroughly to exclude a primary deep-seated intra-oral lesion before regarding a cervical tumor as primary in origin.

5. The highly malignant and cellular nature of the tumor process contraindicates surgical intervention alone in the treatment of patients

with this disease. Their marked susceptibility to radiation, on the other hand, renders these tumors especially suitable for radiation therapy.

6. The ability completely to eradicate the disease in the primary lesion and cervical nodes by irradiation alone has been demonstrated. The advisability of surgical removal of the cervical nodes following heavy dosages of radiation is still undecided. Nine cases controlled for over three years by the combined method as well as by irradiation alone are reported.

#### REPORT OF CASES

CASE 1.—H. B., a man, aged 53, was admitted on April 11, 1917, with the history that about four years before presentation he had noticed an enlarged node on the left side of the neck which had remained quiescent for a long time. About two years before admission, his dentist discovered a mass in the region of the right tonsil which gradually increased in size. Examination showed that the right tonsil was enlarged, nodular and about 3 cm. in diameter. At the angle of the jaw on the right side, there was an enlarged node, 1 cm. in diameter. A specimen taken from the tonsillar lesion was reported on as follows. "Epidermoid carcinoma, papillary and infiltrating, some basal cell features, cells are quite small." Reexamination of this section disclosed the typical histologic features of transitional cell carcinoma. On April 13, radium emanation was applied to the primary lesion as follows: 450 millicuries filtered through 1 mm. of platinum for one and a half hours (total dose, 675 millicurie hours). Three days later, a radium emanation pack was placed over the right side of the neck at a distance of 10 cm., filtered through 2 mm. of lead (1,140 millicuries for ten hours, 11,400 millicurie hours).

On May 8, a dissection of the nodes of the right side of the neck was performed. Microscopic examination showed metastatic transitional cell carcinoma. The largest node was the size of a small hen's egg and was completely replaced by tumor tissue. Sixty millicuries of radium emanation filtered through 1 mm. of platinum was left in the operative wound for four hours (240 millicurie hours). One month later, the tonsillar lesion had completely disappeared, and there was no evidence of cervical adenopathy. There was never any sign of recurrence of the condition in the tonsil or the neck, and the patient became entirely free from disease and in an excellent general condition (eleven years).

CASE 2.—J. R., a woman, aged 44, was admitted on Feb. 4, 1919, with the history that hoarseness and pain on swallowing had developed in 1916. This continued until December, 1918, when a small lump appeared in the left side of the neck, and gradually increased in size. Two years previously, a specimen was taken from the base of the tongue and a diagnosis of sarcoma made. She then received twenty-one roentgen treatments over both sides of the neck. Examination showed the left tonsil to be the seat of a small crater-like ulcer extending onto the tonsillar pillars and the base of the tongue. In the left side of the neck, there was an enlarged node 2.5 cm. in diameter. On Feb. 4, 1919, three glass emanation tubes were inserted into the tonsillar lesion for a total dose of 2,032 millicurie hours, and on April 23, four more emanation tubes were inserted (660 millicurie hours). On Feb. 19, 1919, the enlarged node which was found to be adherent to the jugular vein was removed and the vein resected; 20.2 millicuries in bare tubes were inserted into the tumor bed. Histologic examination showed transitional cell carcinoma in the node. There was no local recurrence after treatment was given, and the patient was free from disease after nine years.

CASE 3.—J. M., a man, aged 59, was admitted on Sept. 8, 1922, with a history of soreness on the left side of the base of the tongue for nine months. Two weeks before admission, a biopsy of the lesion of the tongue showed epidermoid carcinoma. Examination showed considerable redness about the anterior tonsillar pillar on the left side adjacent to the tongue. On palpation, there was a small, irregular, indurated growth involving the left edge of the tongue and extending onto the anterior tonsillar pillar. There was no cervical adenopathy. On September 8, eleven glass emanation tubes were inserted into the primary growth (1,584 millicurie hours). There was prompt regression and disappearance of the primary lesion. On September 8, the patient was given one low voltage roentgen treatment over the right side of the neck, and on September 14, a similar exposure over the left side. On November 1, a node appeared on the left side of the neck; ten days later it was removed, and five glass emanation tubes were buried in the tumor bed. Ten months later, a recurrence was noted in the left side of the neck. The mass was exposed, and twenty glass emanation seeds were distributed throughout (2,439 millicurie hours). Microscopic examination of the cervical node showed metastatic transitional cell carcinoma. The cervical mass responded promptly and disappeared. There was no evidence of disease four and a half years afterward.

CASE 4.—F. N., a man, aged 43, was admitted on Jan. 29, 1924, with a history of dysphagia for ten months. One month before admission, a node was removed from the left side of the neck which on section proved to be carcinoma. Examination showed a bulky growth involving the entire epiglottis and adjacent portion of the tongue. There was a healed scar over the left side of the neck and a diffuse swelling of the soft parts, but no distinctly palpable nodes.

On January 31, nine emanation tubes were inserted into the primary growth for a total dose of 530 millicurie hours. On the two successive days 10,000 millicurie hours of emanation was given over each side of the neck with the radium pack, and one day later a dissection of the left cervical node was performed. Ten emanation tubes were distributed throughout the tumor bed after the complete block dissection (total dose, 1,605 millicurie hours).

Examination of the specimen from the left side of the neck showed muscle, jugular vein and several lymph nodes. One node, 2 cm. in diameter, was found to be replaced by opaque tumor tissue. The other nodes were free. Microscopic examination showed lympho-epithelioma. The primary lesion promptly disappeared, and there was no evidence of disease four years afterward.

CASE 5.—W. B., aged 56, admitted on Sept. 6, 1924, complained of pain on swallowing and of an enlarged node on the left side of the neck, both of six weeks' duration. On examination the left tonsil was found to be enlarged and markedly inflamed with purulent material exuding from the crypts. It was firm and indurated. In the left side of the neck below the angle of the jaw, there was a hard movable node 2 by 2 cm. and a smaller node of the same character. A biopsy specimen from the tonsil showed transitional cell epidermoid carcinoma. The primary lesion was treated with ten glass emanation tubes (1,108 millicurie hours). On September 17, one week later, the patient received one high voltage roentgen treatment over the left side of the neck and the following week a similar dose over the right side of the neck. There was prompt and rapid regression of the primary lesion and metastatic nodes, so that three weeks later there was no evidence of disease in the left tonsil, and the cervical mass was distinctly smaller. On October 3, an incision was made over the left sternomastoid muscle exposing an adherent mass of nodes in the upper deep cervical chain. The internal jugular vein was clamped and divided both below and above the nodes. It was then found

that the mass was so adherent to the deeper structures, especially the carotid artery, that it was considered inoperable. Twelve millicuries of emanation tubes were distributed throughout the mass. One accessible node was removed for microscopic study and showed transitional cell carcinoma. The wound was closed. The following postoperative irradiation was given during various periods when there seemed to be a slight increase in fulness over the operative field. Treatment was followed by prompt regression in each instance. The tonsillar lesion was completely healed, and there was no evidence of disease in the neck four years after operation.

CASE 6.—N. S., a man, aged 40, was admitted on May 20, 1925, with the history of severe headaches, nasal discharge and nasal obstruction developing in January, 1923. In June, 1923, a nasal operation was performed which resulted in temporary relief of the nasal obstruction. One radium treatment in the nasal passages resulted in partial relief of symptoms, but the nasal discharge and

obstruction soon recurred. Several months before admission, a second nasal operation was performed, and observations at biopsy were reported as carcinoma. On examination, the patient presented a bulky tumor filling the nasal passages, more marked on the left side. There was no definite cervical adenopathy. Examination of the tissue removed from the tumor before admission showed transitional cell epidermoid carcinoma. Radiation was administered as shown in table 3.

CASE 7.—L. R., a man, aged 44, admitted on May 18, 1925, had for two months noted soreness and slight bleeding in the left tonsil. Examination showed a large soft swelling of the left tonsil about 2 by 2.5 by 4 cm. The upper half was ulcerated and covered with a grayish slough. In the left upper cervical region, there was a large firm node about 2.5 cm. in diameter. A specimen for biopsy taken from the ulcerated edge of the tonsillar lesion showed transitional cell epidermoid carcinoma. Radiation was administered as recorded in table 4. There was prompt and rapid regression of the primary tumor and cervical node, and the patient remained free from disease until one year later (April 15, 1926) when an enlarged firm node appeared in the right upper cervical region. Radiation was employed as shown in table 5. The node promptly disappeared, and there was no evidence of disease afterward.

CASE 8.—W. J. B., a man, aged 61, was admitted in December, 1924, with the history that six months before presentation he noticed a swelling in the right side of the neck. Four weeks before admission, he began to notice difficulty in swallowing. His general health was excellent. Examination showed two enlarged firm nodes in the right side of the neck. Direct examination of the larynx showed a tumor, about 3 cm. in diameter, lying on the pyriform sinus. Five bare tubes totalling 5.1 millicuries were implanted in the primary growth (total, 673 millicurie hours). Following heavy external irradiation with high voltage x-rays

and the radium pack, a dissection was performed on the right side of the neck. Microscopic examination showed transitional cell epidermoid carcinoma with marked changes due to radiation. The patient's general condition was excellent, and there was evidence of disease after three and one-half years.

CASE 9.—F. C., a man, aged 59, in April, 1925, first noticed slight hoarseness associated with some soreness of the throat and a slight cough. On several occasions, he coughed up bloody sputum. His general health remained good, and there was no loss of weight. Examination revealed a granular ulcerated lesion on the right side of the anterior surface of the epiglottis, near the base, extending onto the right vocal cord. In the right side of the neck, underlying the sterno-

mastoid, was a firm movable node, 2.5 cm. in diameter. Examination of a biopsy specimen from the primary lesion revealed a transitional cell epidermoid carcinoma. The case was considered too far advanced for an attempted curative treatment; consequently, it was decided to perform a tracheotomy and resort to surface irradiation as a palliative measure. Radiation was applied as shown in table 6.

\* For the radium "pack," 10,000 millicurie hours at 6 cm. distance is approximately 90 per cent of an erythema dose. For the radium "tray," at 3 cm. distance, 2,500 millicurie hours is approximately 90 per cent of an erythema dose.

† Sixty minutes of "high voltage" x-rays at 4 milliamperes and 50 cm. target skin distance, with the filter as stated before, is approximately 85 per cent of an erythema dose.

Following irradiation, there was marked regression of the primary lesion and the cervical node. Laryngoscopic examination showed marked radium effect and no evidence of disease, the primary lesion having entirely disappeared. The last examination made on July 20, 1927, revealed no evidence of disease in the larynx and complete regression of the cervical node. This is a remarkable case in that the primary lesion apparently disappeared completely under treatment by external irradiation alone. Three years and three months after the beginning of symptoms, there was no evidence of disease locally or generally, and the general condition of the patient was excellent.

# EXPERIMENTAL SURGERY OF THE ESOPHAGUS\*

JAMES H. SAINT, M.D.

Fellow in Surgery

AND

FRANK C. MANN, M.D.

ROCHESTER, MINN.

Surgery of the esophagus is of interest if for no other reason than that in spite of the time, energy and ingenuity expended on perfection of the technic it still remains largely an unconquered field. This is evidenced by the appalling mortality attending the more radical operations on this structure. As the literature on the development of esophageal surgery has been reviewed elsewhere,<sup>1</sup> little will be said concerning it here, only the experimental problems pertinent to the subject being discussed.

A combination of several circumstances adds to the difficulties of operation on the esophagus, and often it is accompanied by grave risk. The most significant of the factors which make the problems in operations on the esophagus somewhat different from those in surgical procedures on other parts of the gastro-intestinal tract are: (1) anatomic situation; (2) lack of a true serosa; (3) poor blood supply; (4) physical environment, with particular reference to the movement of respiration; (5) strength and character of the propulsion of food material through it, and (6) lack of an omentum to protect and favor healing of the suture lines.

The esophagus is deeply seated throughout its entire course, so that the problem of exposure was the first to occupy the attention of the surgeon. The exposure of the cervical portion was not so difficult and could be accomplished by deep dissection between the carotid sheath laterally, and the trachea and thyroid gland medially. The exposure of the thoracic portion was much more difficult, as the same difficulties that are found in any intrathoracic procedure were encountered. This portion was first exposed by posterior mediastinotomy in an endeavor to avoid opening the pleural cavity, as the latter procedure was known to be fraught with danger of collapse of the lung and pneumothorax. The exposure of the esophagus through the transthoracic route was attempted, but this method of approach was not put on a safe

basis until the invention of the differential-pressure chamber, and later, and more important, the simple method of intratracheal insufflation. It is thus apparent that surgery of the thoracic portion of the esophagus had been dependent on the development of thoracic surgery. Once the problem of exposure was solved sufficiently well, the other causes militating against successful operation soon attracted the attention of the surgeon.

The esophagus does not possess a serous covering. The significance of this is at once apparent. When the bowel is sutured, the peritoneum, in response to the traumatic irritation imposed on it, throws out lymph which coagulates, thereby sealing the line of suture. This mechanism is lacking in the esophagus and, consequently, the safety of the suture of this viscus is greatly impaired. The outer coat of the esophagus consists of connective tissue continuous with that of the structures surrounding it. When the organ is loosened in its bed, the cellular planes of the neck or the connective tissues of the mediastinum are opened, and a risk is incurred because of the danger of ensuing cellulitis or mediastinitis which may take place in spite of the most careful aseptic precautions. This risk is considerably increased if the lumen of the esophagus is opened, because of the infective nature of the esophageal secretion. Coincident with the danger of mediastinitis is that of infection of the pleura, often leading to virulent empyema.

It is the general opinion that apart from the absence of a serosa, the wall of the esophagus forms poor material for suture, both submucous and muscular coats being cut through easily. In this connection it has been found that if the lower third of an esophagus, recently removed from a patient, is divided and then joined by two layers of fine silk sutures, the artificial juncture withstands the pressure of a column of water 6 feet (182.9 cm.) high without the escape of gas or fluid. From this investigation it is clear that the removed esophageal wall has the required strength; the important point which must be borne in mind, however, is that in the living body the strength of any such line of suture depends entirely on a sufficient blood supply.

Unfortunately, the esophagus is poorly supplied with blood, although it is derived from several arteries, namely, the aorta, the inferior thyroids, the subclavians, the left inferior phrenic and the left gastric. The great danger in end-to-end anastomosis of the esophagus is the constriction of the blood vessels by the sutures, which may result in necrosis with perforation of the wall and leakage of the contents. In some cases, antethoracic subcutaneous transposition of the oral end of the esophagus after resection has interfered sufficiently with the blood supply to cause necrosis.

The movements of respiration are also a complicating factor in surgery of the esophagus. Not only do the respiratory movements make

suture difficult at the time of operation, but they also have a tendency to disturb the site of operation and thus the walling off and healing processes during convalescence. The pull of the diaphragm also places the line of suture on tension, particularly if a considerable length of esophagus has been resected. This complicating factor can be avoided by section of the left phrenic nerve before the esophagus is sectioned.

The passage of food through the esophagus is also slightly different from its passage through the remaining portion of the gastro-intestinal tract from both the physiologic and the surgical standpoints. An inhibitory mechanism often places the intestine at rest after it has been operated on. Apparently, the esophagus is not protected in this manner. The food is propelled into it with great force from the oral cavity; peristaltic waves, controlled by an extrinsic mechanism, then sweep the food toward the cardia. It is thus evident that the ingestion of food and water would place a suture line in the esophagus on considerable tension. The line of suture can be protected from injury by the passage of material within it only by the rigid exclusion by mouth not only of food and water, but of all extraneous material, such as bedding and hair. It should also be recalled that the action of the omentum in protecting the lines of suture in gastro-intestinal operations is an important factor in making operation on this structure possible. Such protection is not afforded a suture line of the esophagus.

The object of the experimental work undertaken was to obtain, if possible, a successful method of suture for the end-to-end anastomosis of the esophagus after simple division, and if this was satisfactory, after resection.

The poor nature of the blood supply in particular was forcibly impressed on us in the earliest experiments on the anastomosis of the divided organ. Fatal cellulitis and mediastinitis were the outcome, and necropsy showed not only sloughing of the cut ends of the esophagus constricted by the sutures, but also discoloration of the mucous membrane for several centimeters above and below the level of division corresponding to the length of the esophagus necessarily isolated for the performance of the operation. As these experimental surgical procedures were carried out with the usual aseptic precautions, it was felt that the primary factor causing the fatal infections was not the contamination of the surrounding tissues with esophageal secretion at the time of operation but the sloughing of the line of anastomosis due to constriction of its blood supply by the sutures with resultant leakage of esophageal secretion.

This led one of us (Saint) to investigate the blood supply to the esophagus in the dog. The most satisfactory method was found to be the injection of a medium opaque to roentgen rays with subsequent

roentgenograms. The specimens to be injected were obtained in a manner similar to that used by Demel<sup>2</sup> in his work on the blood supply to the esophagus of human beings. The method of preparation of the specimens, the technic employed for injection and the results obtained, have been described in detail elsewhere.<sup>1</sup> Briefly, the results obtained were as follows:

1. The roentgenograms showed clearly the scantiness of the blood supply to the esophagus. This was strikingly apparent when the small amount of injection medium capable of filling the arteries of the esophagus was contrasted with the large quantity necessary to fill those of the stomach.

2. The blood supply is segmental in type. Most of the arteries divide into ascending and descending branches, and those of one particular segment anastomose with the arteries supplying the segments above and below.

3. The anastomotic network between the arteries of adjacent segments is scanty.

4. The arteries on reaching the wall of the esophagus pass quickly into its submucous layer and there ramify. Microscopic sections of an esophagus, the arteries of which have been injected, show this layer to be by far the most vascular.

5. According to the distribution of its blood supply, the esophagus may be divided into the following segments: cervical, upper thoracic, middle thoracic, lower thoracic and abdominal.

We shall not discuss in detail the arterial supply to each of these segments. We wish, however, to mention that the parts of the esophagus with the poorest blood supply are the middle and upper parts of the cervical segment and the lowest part of the lower thoracic segment. On the other hand, the middle thoracic segment (at the level of the bifurcation of the trachea) is the most vascular part of the canine esophagus.

As we have mentioned, the ability of a line of suture to hold the two cut ends of any viscus together depends primarily on the conservation of sufficient blood to the line of anastomosis. The studies carried out on the blood supply to the esophagus so clearly demonstrated its poverty as to lead to the conclusion that unless special care was exercised it would be an easy matter to produce enough constriction of the blood vessels by the sutures to cause sloughing of the two cut ends, resulting in extravasation of esophageal secretion with fatal infection.

The structure of the esophageal wall must be taken into consideration also. The muscular coat is not suitable for suture as it will easily tear.

---

2. Demel, Rudolf: Die Gefäßversorgung der Speiseröhre: Ein Beitrag zur Oesophaguschirurgie, Arch. f. klin. Chir. **128**:453, 1924.

The submucous layer, on the other hand, is strong and its inclusion in the sutures is essential if the two cut ends are to remain in apposition. Aseptic technic and careful packing off of the divided esophagus from the surrounding tissues are a *sine qua non*.

#### METHOD OF OPERATION

With the foregoing in mind, a technic was devised for the end-to-end anastomosis of a divided esophagus. A brief outline of this technic has been given elsewhere in a report of the results obtained in a series of simple divisions and anastomoses in dogs. The purpose here is to report a series of operations not only on the divided esophagus but on the organ after resection. The essential special steps in the technic are: (1) the employment of a suture material and a method of suture which would conserve the greatest amount of blood supply to the line of anastomosis; (2) placing the esophagus at rest postoperatively by the prevention of the ingestion of anything for several days while the fluid and food are administered intravenously, and (3) partial elimination of the effect of respiratory movement by section of the left phrenic nerve.

Japanese silk number 1 (which is finer and stronger than the thinnest catgut) was used for the suture on a fine, straight needle, number 12, cut down to about half its original length.

The anastomosis was made by two rows of sutures. In most of the operations the inner row consisted of eight or nine interrupted inverting mattress sutures, spaced evenly around the circumference and passing through the whole thickness of the esophageal wall, thus including the strong submucous layer in their grasp. The needle pierced the wall about 2 mm. from the cut edge, and each suture included in its grasp about 2 mm. of the circumference. Thus, while the blood supply to those parts of the esophageal wall caught in the sutures was constricted when they were tied, that of the remaining greater part of the circumference was unharmed. In some of our later operations interrupted single sutures were used. These are easier to insert, they shorten the time of operation and appear to act as stay sutures as successfully as those of the mattress type. They have the additional advantage of improving the conservation of the blood supply to the line of anastomosis.

The outer row of sutures was continuous, passing through only the muscular coat and avoiding the submucosa where the vessels ramify. This outer row inverted the inner and made the anastomosis water-tight.

The operations of simple division or resection with end-to-end anastomosis were carried out in both the cervical and the thoracic parts of the esophagus. Intratracheal anesthesia was used in all cases.

In the neck a median-line incision was made which extended from the cricoid cartilage to the jugular notch, and continued down to the

trachea between the hyoid depressor muscles. It might be mentioned here that this method of approach to the esophagus is much easier than that between the sternomastoid muscle laterally and the hyoid depressor muscles medially. After the pretracheal fascia had been cut through, a finger was inserted backward along the left side of the trachea and hooked around the esophagus which was then brought up into the wound. The recurrent laryngeal nerves, which are adherent to the esophagus, were stripped from it and the viscus isolated by blunt dissection.

The thoracic part of the esophagus was approached by the trans-thoracic route. The incision was made in the seventh left intercostal space, extending almost from the vertebrae to the sternum, and the rib spreader was inserted. Excellent exposure of the esophagus from the arch of the aorta to the diaphragm was thus obtained. The left half of the diaphragm was paralyzed by the removal of about 1 cm. of the corresponding phrenic nerve, and in this way the postoperative tension on the line of anastomosis due to the movements of the muscle was avoided. Both vagi were dissected free from the esophagus for several centimeters. The isolation of the esophagus was not difficult but could never be accomplished without a hole being torn in the right pleural cavity, because the mediastinum below the hilum of the lung is exceedingly thin in the dog, and the parietal pleurae are so closely adherent to the esophagus that attempts to separate it from them always resulted in their being torn. As soon as the esophagus was isolated for several centimeters in either the cervical or the thoracic region, the operation was continued as follows.

Rubber-covered intestinal clamps were applied to the esophagus above and below the part of its wall to be divided or resected (fig. 1, *a*). These clamps were used only to occlude the lumen of the esophagus and so prevent the escape of secretion into the field of operation from either above or below. The pressure exerted by them was not sufficient to injure the blood supply. After the clamps were applied, the esophagus was thoroughly packed off in a manner similar to that used when gastro-enterostomy is to be performed. That part of the viscus between the clamps was then cut through by a scalpel or straight scissors, and the ends turned upward and thoroughly wiped. Then began the application of the technic described for the end-to-end anastomosis of the cut ends of the esophagus. Four or five interrupted inverting mattress sutures were inserted through the posterior half of the circumferences of the cut ends (fig. 1, *b*); the clamps were held close together in order to take the tension off the sutures which were then tied (fig. 1, *c*). The anterior halves of the circumferences were then drawn together by four or five similar sutures, each of these being tied before the next was inserted (fig. 2, *a* and *b*). The clamps were taken off at this stage. The second

row, a continuous suture inverting the first, was begun at the center of the anterior part of the line of anastomosis (fig. 2, *c*). Traction toward the left was put on the short end while the suture was continued to the right (fig. 2, *d*). Each bite of the needle included just so much of the esophageal muscular coat as seemed necessary to prevent the cutting

Fig. 1.—*a*, clamps in position; *b*, esophagus resected, mattress sutures inserted in posterior walls of cut ends and ready for tying; *c*, sutures tied, bringing together and inverting the posterior walls of the cut ends.

through of the silk. When a point about half way around the circumference was reached the needle was passed under the esophagus to the left side (fig. 3, *a*). Traction was then exerted on the short end toward the right, and the suture continued from left to right until the starting

Fig. 2.—*a*, continuation of inverting mattress sutures onto the anterior walls of the cut ends; *b*, completion of inner layer of mattress sutures; *c*, beginning of outer continuous suture in the center of the anterior wall of the esophagus; *d*, suture continued to the right while traction is made on the short end toward the left.

point was again reached (fig. 3, *b*). In this way the entire circumference of the esophagus was sutured with ease. This method of performing the outer continuous suture is technically easier than putting in its posterior half before the introduction of the mattress sutures, as in gastro-enterostomy.

In a few instances the end-to-end anastomosis was performed without clamps. When these were omitted the two cut ends were held in apposition until the inner row of interrupted mattress or single sutures had been inserted by two stay sutures which passed through the entire thickness of the esophageal wall. This procedure did not give better results, and it was technically much easier to work with clamps.

The postoperative treatment is of great importance in the success of the operation. In our experiments it consisted in placing the esophagus at rest for seven days by not giving any food or water by mouth during this period. Water balance and nutrition were maintained by 10 per cent dextrose solution in a physiologic solution of sodium chloride administered intravenously in quantities varying from 200 to 350 cc. a day, according to the weight of the dog. At the end of a week the animal was allowed a mixture of milk and syrup for seven days, after which an ordinary diet was given.

#### RESULTS

The first six operations in which this technic was used were simple divisions of the esophagus and were carried out on the cervical part at different levels. The following is a summary of the results obtained.

In only one animal did the line of suture slough with an ensuing infection. In the remaining animals the blood supply to the line of anastomosis was conserved sufficiently to prevent sloughing. In the animal in which sloughing of part of the line of anastomosis occurred the operation was performed on the most vascular (lower) region of the cervical part of the esophagus, and as a successful operation was performed later in the same region, the failure can be attributed only to faulty technic. Four of the operations in which the line of anastomosis held successfully were performed on the least vascular (upper and middle) regions of the cervical part of the esophagus.

A small degree of stricture occurred in two animals, probably the result of grasping too much of the circumference of the wall of the esophagus by some or all of the mattress sutures, an imperfection in technic which was remedied later. Two of these animals are under observation and in good condition 376 days after operation (Jan. 1, 1929).

The results of these operations showed that this method of suture permits a supply of blood to the line of anastomosis sufficient to prevent

Fig. 3.—*a*, half the circumference has been sutured; the needle is now passed behind the esophagus to the left side and the short end of the suture is now passed to the right; *b*, traction of the short end toward the right and continuation of the suture from left to right; *c*, anastomosis complete.

sloughing and ensure union, even when the esophagus is divided in the least vascular of its cervical part.

Before beginning the resection of varying lengths of the esophagus we decided to try division of the least vascular part of its thoracic portion, that is, the 2 to 3 cm. adjacent to the diaphragm. Three operations were performed, and the results obtained show that this method of suture

Fig. 4.—Lower end of the thoracic part of the esophagus removed 107 days after operation, showing healed line of suture.

ensured a blood supply to the line of anastomosis sufficient to avoid sloughing even in this scantily supplied portion of the esophagus. Empyema occurred in two animals, but the line of suture in each instance remained intact. One operation was successful in every respect (fig. 4).

The results following the use of this method of suture for end-to-end anastomosis of the divided esophagus were encouraging enough to warrant the investigation of its efficacy after resection of varying lengths

of the organ, when considerably more tension would be put on the line of suture than after simple division.

In only one of the four operations in which the esophagus was resected in the cervical portion did sloughing of the line of suture occur with ensuing fatal infection, although this was localized and had not extended into the mediastinum. The other three operations were entirely successful. A slight degree of stenosis found at necropsy in two of the animals was purely anatomic, and, judging from the good health of the animals up to the time of necropsy, it did not have any functional signifi-

Fig. 5.—Specimen distended with water, removed 145 days after operation. A slight decrease in size of the lumen has occurred.

cance as they ingested their food in a perfectly normal manner. A maximal length of 4 cm. of the cervical part of the esophagus was resected successfully (figs. 5, 6, 7 and 8).

Three of five animals in which resection of the thoracic part of the esophagus was performed survived in each case with a perfect functional result (fig. 9). In only one case did the line of anastomosis slough with a fatal result. The other death was due to hemorrhage, and its most likely source seems to have been the intercostal artery posteriorly near the vertebral column. On a few occasions complete hemostasis in this

area was difficult to obtain. One of the animals is under observation and appears to be normal 301 days after operation (Jan. 1, 1929).

Four centimeters of esophagus was successfully resected. This was approximately one seventh of the total length. In certain portions of

Fig 6—Mucosal surface of specimen shown in figure 5. The thinned raised ridge which marks the site of section appears greater than it really is, as shown in figures 7 and 8.

Fig 7—Longitudinal section through line of anastomosis of specimen removed 145 days after operation. The line of anastomosis is hardly discernible,  $\times 100$ .

the esophagus it would seem entirely feasible to resect a longer segment successfully. It should be noted that the results reviewed included all the operations performed by this technic. Most of the unsuccessful operations occurred during the development of the method and were due

Fig 8—A higher magnification of a portion of the section shown in figure 7,  
 $\times 500$

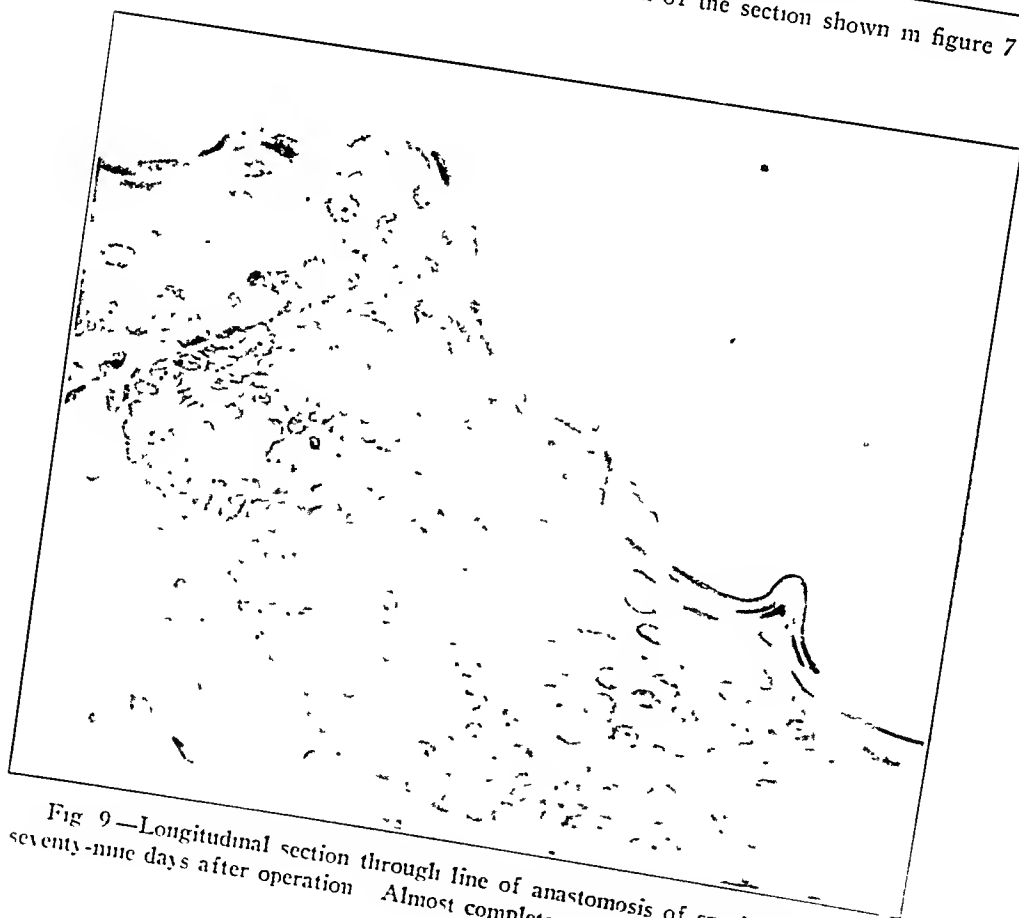

Fig 9—Longitudinal section through line of anastomosis of specimen removed  
 seventy-nine days after operation. Almost complete repair has occurred;  $\times 12$

to faults which were later corrected. We are confident that once the technic is developed a high percentage of success can be obtained. Whether or not any portion of the technic can be adapted to human beings cannot be determined at present. Experimentally, however, section or resection of the esophagus can be accomplished successfully.

#### SUMMARY

A method for section and resection of the esophagus is described. The essential special procedures are: (1) the employment of an interrupted suture of fine silk in order to conserve the blood supply to the line of anastomosis; (2) sectioning of the left phrenic nerve in order to help immobilize the site of operation, and (3) preventing the animal from taking anything by mouth, and maintaining its nutrition with intravenous injection of dextrose and sodium chloride in order to place the esophagus, as much as possible, at physiologic rest. This method has proved successful in experimental surgery.

# CONGENITAL ATRESIA OF THE BILE DUCTS

## ITS DIAGNOSIS AND A CONSIDERATION OF SURGICAL INTERVENTION ON THE BASIS OF ITS PATHOLOGY \*

LESTER ROSENBERG, M.D.

AND

GEORGE E. JUDD, M.D.

BROOKLYN

Though a relatively large number of cases of congenital atresia of the bile ducts has been reported, attention has been restricted for the most part to the academic, if interesting, discussion of the anomaly at autopsy and to the possible etiologic factors involved. Little has been written on the management of these cases. Little has been said in reference to the worth of therapeutic procedure and the indication for surgical intervention. We report a case in which attention is focused on the problem of what to do for the child. We present the difficulties which confronted us in establishing our diagnosis and the perplexities which troubled us in planning our therapy. We shall, therefore, discuss in some detail the problems of differential diagnosis, but more especially do we wish to take up the question of the wisdom of surgical intervention on the basis of the underlying pathologic changes.

### REPORT OF A CASE

*History.*—A. R., a white girl, aged 3 months, was admitted to the Pediatric Service of the Brooklyn Hospital on Feb. 14, 1928, the chief complaints being cough and fever of three days' duration and jaundice and white stools since birth. From birth to the time of admission, the mother had noticed an increase in the depth of the jaundice. The patient was the sixth child in the family, a full-term infant, delivered by a midwife, with an ambulance physician in attendance. The labor was easy and of short duration. It was noted at birth that the skin and sclerae were yellow. Otherwise, the child seemed normal. There was no desquamation of the palms or soles, no fissuring and no snuffles.

The child was given the usual care for the new-born infant, but developed an umbilical infection which persisted for two months, during which time there was a profuse yellow purulent discharge from the stump. There was apparently no fever. The child was put on three hour breast feedings and apparently gained weight, although vomiting occurred occasionally during the second and third months. The mother noticed that the stools were always either white or light gray and rarely faintly yellow. There were about three or four a day; they were well formed, without curds and with no apparent increase in bulk. There was no foul odor. The urine was persistently dark brown.

---

\* Submitted for publication, Feb. 9, 1929.

\* From the Pediatric Service of the Brooklyn Hospital (service of Dr. A. D. Smith).

Three days before admission, on Feb. 11, 1928, the child had some fever, cough and anorexia, and was taken to the Children's Clinic for treatment. The family history was essentially negative, with no history of miscarriages or stillbirths. Both the father and the mother were well. Five other children, all boys, were living and well. The Wassermann reaction of the blood of the father was 3 plus; that of the mother was negative on two occasions. The Wassermann reactions of the blood of the five children were all negative.

*Examination.*—On examination, the patient showed an intense uniform jaundice. The pharynx was injected. There were many medium and fine moist râles throughout both lungs, without any definite signs of consolidation. The abdomen was slightly distended. The liver dulness in the midclavicular line extended from the fifth rib above to 6.25 cm. below the costal margin, and in the axillary line to the anterosuperior spine. Its surface was hard but apparently not irregular, and the child manifested no apparent discomfort when it was palpated. The spleen was palpable 3.5 cm. below the costal margin. It was smooth and firm, but not tender. The observations in the physical examination were otherwise negative.

The temperature was 102 F., the pulse rate 110 and the respirations 35. The white blood cell count was 23,400, with 70 per cent polymorphonuclears and 30 per cent lymphocytes. The hemoglobin content was 72 per cent. The urine was dark brown, with a faint trace of albumin and a markedly positive reaction for bile. The Wassermann reaction of the blood was negative on two occasions. Daily examinations of the stools showed a slight trace of bile by Gmelin's test on two occasions; at all other times the reaction for bile was negative. The fragility of the red blood cells began at 0.4 per cent and was complete at 0.325 per cent. The coagulation time was six and a half minutes; the bleeding time, two minutes. The results of the intradermal tuberculin test, 0.1 mg., were negative. Roentgen examination of the chest showed increased density at each hilum with increased infiltration in the right lower lobe and patches of density well out in the axillary line just above the diaphragm.

*Treatment and Course.*—The patient was put on routine treatment for pneumonia in infants—mustard plasters to the chest every four hours, tincture of digitalis, forced fluids and feedings of 3 ounces (89 cc.) of 50 per cent skimmed milk (boiled skimmed milk and boiled water, equal parts) every three hours, supplemented by breast milk from the mother when obtainable.

On February 15, the temperature returned to normal. The patient seemed much better and took all the feedings well. A somewhat bothersome cough persisted.

On February 17, examination of the chest showed a few scattered râles at both bases but no dulness. The breath sounds were harsh but distinctly vesicular.

On February 21, the signs in the chest, previously described, were no longer present. The drum of the right ear ruptured spontaneously, liberating a small amount of bloody serum.

Influenced in part by the positive Wassermann reaction of the blood of the father and in greater measure by repeated urgings to try antisyphilitic treatment, we instituted, against our better judgment, a course of such therapy, even though no stigmas of syphilis were present and the Wassermann reaction of the blood had been negative on two occasions.

On February 26, 0.03 Gm. of sulpharsphenamine was given intramuscularly with no untoward reaction, and doses of 0.04 and 0.05 Gm. were given on March 3 and 12, respectively, with no harmful results.

On March 15, the child was discharged to the outpatient department for continuation there of antisyphilitic treatment and follow-up. The respiratory symptoms had cleared entirely. The jaundice was of the same intensity. The liver and spleen were about the same size as at the time of admission.

On March 26, the patient was seen in the outpatient department. Her condition was little changed; the jaundice was of the same intensity; the temperature was 100.4 F. She had gained 10 ounces (283.5 Gm.) since the previous visit.

On April 7, 0.5 grain (0.03 Gm.) of mercuric salicylate was given intramuscularly. This was followed in a few hours by fever and vomiting. The child appeared quite ill and the mother reported that she thought that the jaundice had deepened. Abdominal distention occurred, but after about forty-eight hours the apparent ill effects of the injection had disappeared.

On April 14, the intramuscular injection of 0.5 grain of mercuric salicylate was followed by a repetition of the illness observed subsequent to the injection of mercury of the previous week, namely, anorexia, malaise, vomiting, fever, abdominal distention and increase in the depth of the jaundice. Some bright red blood tinged the stools, but at no time were they dark or tarry. The antisyphilitic treatment was discontinued.

On April 18, the child was again seen in the outpatient department. She had lost 6 ounces (170 Gm.) since March 26, and the general condition seemed so much worse that admission to the hospital was advised.

On admission, it appeared that the general nutrition of the child had evidently suffered since the time of discharge, almost five weeks before. The jaundice was possibly a little deeper than at that time. The gums were somewhat swollen and reddened. The heart and lungs were normal. There was moderate abdominal distention. The liver was now 10 cm. below the costal margin in the midclavicular line, and the spleen 6 cm. below the costal margin. Both organs were hard, not tender, and apparently smooth. The temperature was 102 F.

The child was put on a skimmed milk diet, 6 ounces (178 cc.) of the following being given every three hours:

Skimmed milk .....	24 ounces	(710 cc.)
Dextrimaltose, no. 1.....	1 ounce	(30 cc.)
Water to make.....	36 ounces	(1,065 cc.)

The urine was dark amber, but was negative for albumin, sugar and acetone; bile was definitely present. Colonic irrigations were necessary to control the distention.

On April 20, the temperature returned to normal and remained so for three days. The general condition of the child seemed much better. The size of the liver and spleen and the depth of the jaundice were unchanged.

On April 23, all the feedings were taken poorly. Abdominal distention was still a disturbing feature.

On April 25, the temperature rose to 102.5 F., but despite this the child's general condition seemed somewhat better and the distention was less. Nothing definite could be found to account for the rise in temperature.

On April 27, the temperature remained elevated, although there was no demonstrable cause. At 6 p. m., a large amount of curdy material was vomited. At 10 p. m. and at 2 a. m., the child took her feedings well, but she vomited a slight amount of the 2 a. m. feeding. The respirations rose to 50 per minute. At 2:30 a. m., the child became cyanotic, and there was marked abdominal distention which was somewhat relieved by colonic irrigation. The infant's condition did

not seem immediately grave, but at 3:30 a. m., after vomiting bloody material, she became cyanotic and died rather suddenly.

*Autopsy.*—The body was that of a poorly nourished girl of about 5 months of age. The skin was deeply jaundiced and dark greenish yellow. The abdomen was enlarged and prominent. On ventral incision, the subcutaneous tissues appeared deeply jaundiced. The parietal peritoneum and pleura were deeply icteric.

The lungs were of normal appearance, were light pinkish red and contained air in all parts. The cut section was normal.

The heart was normal in size and shape. The intimal surfaces of the aortic and pulmonary valves were deeply bile-stained. The heart was otherwise normal.

The liver was large, weighing 175 Gm., of normal shape and dark greenish brown. It was hard and the surface was finely pebbled. On section, it cut with increased resistance. The cut surface was dark greenish brown. The gallbladder was present as a slender, elongated structure in a deep but narrow gallbladder fossa. The lumen of the gallbladder was readily found. It contained no bile and the walls were thin; the inner surface was pale yellowish white. The portal vein and hepatic artery were readily found in the edge of the gastrohepatic omentum, but no structure identifiable as a common bile duct could be found. It appeared to have been absent congenitally. The cystic duct was traceable a short distance from the neck of the gallbladder, but appeared to end blindly in a fibrous strand in the gastrohepatic omentum.

The intestines were moderately dilated with gas and fluid contents; the mucosa was deeply jaundiced. Section down the duodenum showed no structure with the appearance of a papilla of the bile duct.

The spleen was large and extremely firm, weighing 75 Gm. The capsule was normal. On section, the cut surface was dark brownish red; no follicles were visible.

The kidneys were of normal size and shape, slightly firmer than normal and so deeply jaundiced that the renal markings were greatly obscured.

The anatomic diagnosis was: congenital atresia of the bile ducts; splenomegaly, and icterus, general.

*Histology.*—Microscopic preparations from the liver showed marked periportal fibrosis, obviously of long standing. The bile radicles of all sizes were filled with thick pellets of bile. Sections through the gastrohepatic omentum showed the portal vessels and disconnected islets of epithelium of the hepatic and common bile ducts, but no epithelial lined lumen was demonstrable. The incorporation of bile pigment by Kupffer's cells was practically absent.

Sections of the spleen showed that the increase in size was mainly due to thickening of the walls of the venous sinuses, distention of the venous channels and increase in the size of the endothelial cells which lined the sinuses. The endothelial cells of the sinuses and the large clear cells of the splenic follicles contained black pigment in the form of coarse granules and globules.

The epithelium of the kidney was granular, and the jaundice that was so obvious grossly was practically imperceptible histologically. The changes in the kidney appeared to be confined strictly to the tubule cells which were enlarged and granular.

Examination of the epiphyseal and diaphyseal lines of the long bones showed no evidence of syphilis. There was no osteochondritis.

Fig. 1.—The liver and spleen, showing the relative sizes. The slender and collapsed gallbladder should be noted.

Fig. 2.—Section through the liver, showing dilated radicles of the gall duct filled with bile. The mottling due to cirrhosis should be noted.

Fig. 3.—Section through the liver, showing the solid cord containing the hepatic vessels. Note the absence of radicles of the gall duct at this level, taken 1 cm. below that shown in figure 2.

## COMMENT

Though there was little doubt clinically that the jaundice was due to a congenital atresia of the bile ducts, there were several disturbing factors which required consideration. First, the history of a chronic infection of the umbilicus for two months suggested an infectious basis for the condition and, secondly, the presence of a 3 plus Wassermann reaction in the father pointed to syphilis as a likely cause.

The absence of a rise in temperature or other signs of sepsis in the general appearance of the infant and the duration of the jaundice spoke strongly against a septic condition. Syphilis, we believed, could be excluded with a fair degree of certainty in view of the absence of any syphilitic stigmas and of a response to antisyphilitic therapy.

One other cause of contention was the presence on two occasions of traces of bile in the stools. These were specimens of enemas, uncontaminated by urine, that gave rise to speculation as to the presence of complete as against incomplete atresia or stenosis. It was postulated then, and evidently correctly, that a deeply stained intestinal mucosa might possibly ooze bile into the lumen of the intestinal tract, or that desquamation of sufficient bile-stained epithelial cells might occur to stain the fecal contents, even though complete atresia was present. The deeply stained mucosa disclosed at autopsy made it appear certain that this was the mechanism for the appearance of bile in the stools.

From a clinical standpoint, the general well-being of the child, despite the complete shutting off of bile from the intestine and the resulting intense jaundice, is most interesting. Although vomiting occurred occasionally, the nutrition was generally well maintained and the child gained surely, if slowly.

How long, then, may life go on in the presence of complete obstructive jaundice?

Lavenson<sup>1</sup> reported a series of sixty-two cases, in which only three patients lived longer than three months, two for nine months and one for eleven months. The majority of patients lived more than four weeks. Several unprecedented cases of long life have been reported, but these apparently did not occur in instances in which complete atresia of a congenital nature was present. Treves<sup>2</sup> reported a case of obstructive jaundice of sixteen years' duration, coming on at the age of 3 years; he operated on the patient at the age of 19. At operation, the cystic and the hepatic ducts were normal and joined to form a common duct which ended almost at once in a hard fibrous nodule which was placed transversely to the long axis of the duct. The

---

1. Lavenson: J. M. Research **13:61**, 1908.

2. Treves: A Case of Jaundice of Sixteen Years' Standing Treated by Operation, Practitioner **62:18**, 1899.

common duct was one-half inch (1.27 cm.) in length. It was impervious at its distal extremity and ended abruptly at the fibrous nodule, beyond which no trace of a duct could be discovered nor was any duct noted entering the duodenum.

As an explanation for the lengthy survival in this case, Wangensteen<sup>3</sup> offered the explanation that the obstruction was produced slowly, thus affording time for replacement of connective tissue and preventing rapid destruction of liver cells which, rather than retention of the toxic constituents of the bile in the blood and tissues, he postulated to be the cause of toxemia and death.

#### PATHOGENESIS

We shall not attempt to review the much debated question of pathogenesis. Much has been written on this subject. Thomson,<sup>4</sup> Rolleston and Hayne,<sup>5</sup> Lavenson<sup>1</sup> and others propounded theories to account for the occurrence of atresia. Much difference of opinion still exists as to whether the condition is congenital in the sense of an anomaly of development or whether an inflammatory process is at the basis of it. Holmes,<sup>6</sup> and Howard and Wolbach<sup>7</sup> reviewed thoroughly the conflicting theories thus far presented. The problem deals with embryologic development of which there is no exact knowledge, and it is probable that we are still a long way from understanding the precise mechanism of the causation of obliteration.

#### PATHOLOGIC ANATOMY

Holmes<sup>6</sup> depicted graphically the anatomic condition present in the cases reported up to his time. The cystic duct, the hepatic duct and the gallbladder may or may not be present. In many cases only a vestige of these structures is found. There is, of course, no passageway for bile to enter the duodenum. The liver is usually increased in size, although atrophy has been noted. It is leathery, tough and firm; the surface is irregular, granular and usually dark green. The cut surface reveals an increased amount of connective tissue. The spleen is often enlarged. Aside from the jaundice, which is general, there is nothing noteworthy in the other organs.

## HISTOLOGY

Histologically, a biliary type of cirrhosis is present. The bile capillaries are usually filled with dark brown thickened bile. There is a marked increase in connective tissue which replaces the liver cells in many of the lobules.

The study of the spleen in our case appears to afford what is, perhaps, another explanation for the enlargement of that organ in connection with cirrhosis of the liver. Microscopically, there is an increase in the size and number of the endothelial cells which line the venous loops and sinusoids. These cells are filled with a dark pigment, suggesting that the endothelial system of the spleen has taken up the function of the liver in removing these substances, which are undoubtedly related to the cholemia. This endothelial cell hypertrophy and proliferation, more than the accompanying venous stasis resultant on the cirrhosis of the liver, appears to account for the enlargement of the spleen.

## DIFFERENTIAL DIAGNOSIS

*Icterus Neonatorum.*—This benign, almost physiologic type of jaundice has been variously reported in from 30 to 80 per cent of all newborn infants. Definite recession usually occurs, even in the severe cases, by the end of the second week, although in exceptional cases it has been known to last as long as five weeks. Bile is present in the stools. There should be no difficulty in differentiating this condition from that due to complete atresia of the bile duct.

*Icterus Gravis Neonatorum.*—This rare condition is usually fatal in the first few weeks of life. The cases in which the patients survive for a longer period may be differentiated from congenital atresia of the bile ducts by the presence of bile pigment in the stools. The disease, too, is often associated with cerebral manifestations—irritability, hyperesthesia, crying attacks, spasticity of the extremities and sometimes of the muscles of the trunk.

*Chronic Interstitial Hepatitis.*—From interstitial hepatitis, the differential diagnosis is often most difficult. In the early weeks of life, the diagnosis may well be in doubt. Munns'<sup>8</sup> case clinically so closely resembled atresia of the bile ducts that it was diagnosed as such during life. His patient developed jaundice at the age of 18 days; the stools at first were yellow and two days later became clay colored. The infant continued to gain weight steadily while under observation the first few months of life, and the general condition seemed good. At about 4½ months, examination revealed a small, markedly jaundiced, poorly nourished male infant, not acutely ill. There was some evidence

8. Munns, G. F.: Chronic Interstitial Hepatitis, *Am. J. Dis. Child.* **31**:469 (April) 1926.

of rickets. The liver was 4 cm. below the costal margin. The spleen was enlarged. The stools were acholic. The Wassermann reaction of the blood was negative. The van den Bergh test gave the indirect reaction. The stools continued to be acholic for the most part, but were occasionally yellow. The child continued to do remarkably well during the first year, despite the jaundice. At 14 months, examination revealed an undernourished, markedly jaundiced infant who could sit alone but could not stand. The abdomen was distended and the liver reached to the umbilicus. Operation was advised but refused. The jaundice progressed; ascites developed, requiring paracentesis, and 450 cc. of straw-colored fluid was removed. The van den Bergh test gave the direct reaction in blood and ascitic fluid. The stools, however, varied from yellow to brown and there were from one to three movements daily. The anemia became progressive. Fluid continued to reaccumulate in the abdomen, and paracentesis was necessary twice. The child continued to grow worse. The temperature rose gradually to 103.8 F. Signs of congestion were present in the lungs, and death ensued at the age of 15½ months.

Autopsy revealed that the ampulla of Vater and the common, hepatic and cystic ducts were patent. The common bile duct averaged from 3 to 6 mm. in circumference. The gallbladder was adherent to the mesocolon and the colon by firm fibrous adhesions. The liver was firm and dark olive green; the capsule was thin and transparent and the surface smooth. The spleen was slightly enlarged. The pancreas was normal.

Microscopic section of the liver showed an extensive chronic interstitial hepatitis. There was an abundance of brown pigment in the large epithelial cells.

*Syphilitic Hepatitis.*—This disease presents difficulties similar to those encountered in chronic interstitial hepatitis. Indeed, the case described under chronic interstitial hepatitis is in all respects similar to the clinical picture manifested by syphilitic hepatitis. In most cases, however, the presence of other stigmas of syphilis, the family history and the parental and the patient's serology in the blood or spinal fluid are of the greatest aid.

*Icterus of Septicemia.*—Differentiation from the jaundice of sepsis is usually made by the character of the temperature, the toxemia, the local umbilical infection often present, the presence often of a bacteremia, hemorrhages from the cord, bleeding into the skin and mucous membranes and the usual rapidity of the course in a septic condition.

*Cholelithiasis.*—Though this condition in infancy is extremely rare, cases have been observed. Still<sup>9</sup> remarked that cases are "commoner

---

9. Still: *Common Disorders of Childhood*, ed. 3, New York, Oxford University Press, 1920, p. 304.

in infancy than at any other period of childhood." Of twenty-three cases described by this writer, "fifteen were in infants and fourteen of these were infants under 10 months of age. In several of these there was intense jaundice at birth or shortly afterwards, and calculi were found in the ducts. In one of my own cases minute calculi were found impacted in the common duct in an infant aged 9 months, but there had been no jaundice."

*Acute Catarrhal Jaundice.*—As rare as congenital atresia is, acute catarrhal jaundice in the first few weeks of life is probably rarer. Cases do appear in the literature from time to time, and it is important that one know its manifestations in considering jaundice in infancy. Henoch<sup>10</sup> observed one case in an infant at the age of 8 weeks and another at 5 months. Flesch<sup>11</sup> reported one case in an infant under 1 year in 160,000 admissions to the Stefanie Children's Hospital in Budapest; his patient was 1 month old. Skormin<sup>12</sup> reported three cases in infants—one at 1 month, one at 14 days and one at 4 days—who died. Postmortem examinations showed duodenitis with hemorrhage into the brain and meninges. The infant, aged 14 days, died, and a colon bacillus and a few cocci were cultivated from the blood and liver. No hepatitis was present. In view of the course and the observations at autopsy in these two cases, it is questionable whether they were primarily instances of acute catarrhal jaundice. In a series of 430 cases of acute catarrhal jaundice reported by Neumann<sup>13</sup> in Berlin, six were in the first year of life, one each at the age of 56 days, 2½ months, 4 months, 8 months and 9 months. Of Langer's<sup>14</sup> 144 cases, only one occurred during the first year of life. In recent years, Hempelman<sup>15</sup> reported three cases in infants—one, aged 8 months, one, 11½ months, and another, 2 months. In all his cases, the duration of the jaundice was short; in the first, six days; in the second, from about a week to ten days, and in the third, about two weeks.

The differential diagnosis of congenital atresia of the bile ducts from acute catarrhal jaundice should never be difficult. The short

duration of catarrhal jaundice at once distinguishes it from malignant atresia.

#### TREATMENT

Porter,<sup>16</sup> writing in Abt's *Pediatrics*, remarked "there is no treatment that can be undertaken with any hope of success." Yet, from an anatomic standpoint, it would seem that if surgical intervention could effect the opening of a channel for bile to reach the intestine, a cure ought to be effected. But why has surgical intervention thus far failed to hold out the hope expected of it?

First, in only 16 per cent of the reported cases has operation been anatomically possible; i.e., sufficient structure was present to allow the creation of a passageway for bile to reach the intestinal tract. Secondly, the degree of hepatitis may be extremely marked and the radicles of the intrahepatic bile ducts so obstructed that what appears to be an adequate external outlet for the bile does not at all solve the problem.

Parsons and Hickmanns<sup>17</sup> reported the case of a patient with biliary cirrhosis with atresia of the extrahepatic bile ducts. Their patient developed a severe, continuous jaundice at the age of 3 weeks, which persisted until death at 6 months. The infant was full-term, breast fed for two weeks and fed thereafter on milk prepared by a formula only. With the onset of the jaundice, the urine became dark and the stools clay colored. On admission, the child appeared well nourished and weighed 8 pounds and 10 ounces (3.9 Kg.). The liver was enlarged, firm and reached almost to the umbilicus. The spleen was not felt. The Wassermann reaction of the blood was negative. In the course of the illness, the jaundice varied slightly in degree, though a fortnight before death it was less marked than it had ever been. Vomiting occurred only once. The infant lost weight gradually and died rather suddenly about sixteen weeks after admission. The weight at the end was 7 pounds and 6 ounces (3.38 Kg.).

They noted:

. . . we feel that this case lends little support to the view that the cirrhosis follows on a developmental defect of the bile ducts, but suggests that whatever may be the cause of the condition, it is one which attacks the liver parenchyma at as early a stage as the bile ducts and offers definite evidence that the whole process may be an intra-hepatic one. If this view is correct, surgical intervention, at any time after the diagnosis is made, cannot offer any chance of complete recovery, because a marked cirrhosis of the liver must be present. In this patient, surgical treatment would obviously have been quite useless.

17. Parsons, L. G., and Hickmanns, E. M.: Biliary Cirrhosis, *Am. J. Dis. Child.* **31**:459 (April) 1926.

Von Reuss,<sup>18</sup> on the other hand, was of the opinion that, "in view of the impossibility of spontaneous recovery, an operation a priori is by no means to be set aside; it should be undertaken, if not during the first few days, in any case as early as possible."

Holmes<sup>9</sup> studied carefully the anatomic anomaly present in the cases reported up to 1916, and observed that in the series of cases in which operation was anatomically possible six of the patients died before the twentieth day of life and nine lived from two to six months. Of the cases in which operations were performed, Giese's<sup>19</sup> was unsuitable. In Oxley's<sup>20</sup> case, only a paracentesis of the tumor was done, with removal of 36 ounces (1.065 cc.) of bile. Theoretically, this was an operable case. Morse and Murphy's<sup>21</sup> case was inoperable, and Putnam's<sup>22</sup> operation was unsuccessful. Treves's<sup>23</sup> case, although successful, leaves great doubt as to the congenital nature of the obstruction.

Until the recent publication of Ladd,<sup>23</sup> we could find no case on record of undisputed congenital atresia of the bile ducts in which operation was successful. This author reported successful operations in six cases of stenosis and atresia of the bile ducts, but of these only the first and third cases were complete congenital atresia, the others being stenosis or obstruction not congenital in origin. It is most hopeful and instructive to know that the first patient, operated on at the age of 3 months, has survived two years; the second patient, operated on at 5 months, has survived seven years. Both were alive when this paper was written.<sup>24</sup>

Though we recognize the courage and skill with which, in these two instances, this seemingly hopeless disease has apparently been mastered, we cannot help but believe that in only the most exceptional cases of congenital atresia of the bile ducts, even though operation is anatomically possible, is it likely that the patient will survive a long period, owing to the cirrhosis of the liver, which is as much a part of the disease as the atresia itself. That exploratory surgical intervention should be tried, we do not deny, but that much can be expected of it, we doubt.

24. Ladd, W. E.: Personal communication to the authors.

One does not like to believe that the older surgical procedure should have been so lacking in technic that no patients prior to the one of Ladd should have been reported as cured. Yet there is much to be said for the development in late years of a finer surgical technic in operation on infants. With it has come the recognition that minimal and gentle handling of tissues plus the element of time are essential to a successful outcome. It is to be hoped that the number of recoveries reported will grow with the appreciation of the necessity for special surgical skill during this early period of life. One should never lose sight of the necessity for early operation in these cases, but no caution is too great to make certain of the diagnosis of atresia of the bile duct.

Only recently, one of us had occasion to observe in another clinic a case of a fairly well marked jaundice in an infant, aged 3 weeks, which had come on shortly after birth. The stools occasionally were acholic, but for the most part were faintly yellow. Permission for studying the child's serology could not be obtained, but that of the parents was normal. There was no evidence of syphilis. Hospitalization was refused, the parents being persistent in their opposition to any study of the case. The child was taken regularly to the clinic, and after three months the jaundice had almost entirely disappeared; the child was doing well at the time this paper was written. What over-enthusiastic surgical intervention, advocating early operation in cases of protracted jaundice, might have wrought in this frail infant is left to conjecture.

On the basis of our experience in giving antisyphilitic treatment in our case, although no evidence of syphilis was present, we believe that in cases of protracted jaundice in the new-born infant in whom there are no serologic or clinical evidences of the disease, the institution of such antisyphilitic treatment is not advisable. Since vomiting and a general intestinal upset followed the administration of mercury, it is easy to understand that a liver already diseased, as it is in congenital atresia, should not bear too well the burden of added toxic substances, such as mercury or arsenic. The severity of a syphilitic infection which would cause protracted jaundice in a new-born infant as a result of interstitial hepatitis has in all likelihood, already damaged the organism beyond repair. Confirmation of this is found in the general agreement among observers that severe jaundice is not commonly observed in the ordinary type of syphilitic cirrhosis.

#### CONCLUSIONS

1. In congenital atresia of the bile ducts, in addition to the anatomic obstruction which prevents bile from reaching the intestine, there is marked cirrhosis of the liver which at the time of birth is as much a part of the disease as the atresia itself.

2. The cirrhosis of the liver is so advanced that, even should surgical exploration reveal an apparently operable condition from an anatomic standpoint, the possibility of effecting a cure is not likely.

3. Surgical intervention in cases of protracted jaundice in infancy, diagnosed as congenital atresia of the bile ducts, should be undertaken, but with a full knowledge of the overwhelming odds, both as to anatomic operability and as to the likelihood of affording a cure even when anatomically operable.

4. In cases of protracted severe jaundice in the new-born infant in whom a positive Wassermann reaction and other stigmas of syphilis are absent, a course of antisyphilitic treatment does not appear logical.

5. Traces of bile may be present in the stools of an infant with congenital complete atresia of the bile ducts.

6. The enlargement of the spleen in congenital atresia of the bile ducts appears to be due in great measure to an increase in the size and number of the endothelial cells which line the venous loops and sinuses of the spleen and suggests an attempt on the part of the spleen to assume the phagocytic function of liver cells which have been damaged.

# TUMORS OF THE BONE

## A COMPARATIVE STUDY \*

WILLIAM H. GOODWIN, M.D.

UNIVERSITY, VA.

In approaching a study of tumors of the bone, one is immediately confronted with a chaos of unsolved problems, pertaining particularly to the osteogenic sarcoma and the giant cell tumor.

Until 1920, when Codman<sup>1</sup> instituted the Registry of Bone Sarcoma, the literature was in a state of confusion because of no satisfactory, workable nomenclature. In this country the writers on this subject are conforming more and more to the classification of bone tumors recommended by the registry committee.

In his able and helpful study of the material of the registry, Kolodny<sup>2</sup> found fault with the classification adopted by the committee and explained his criticism on the grounds that when the classification was made, the material was not so plentiful as now, and that the personnel of the committee consisted chiefly of laboratory men. He recommended the following classification for the primary malignant tumors of the bone, which is not essentially different from the one adopted by the committee:

1. Osteogenic sarcoma.
2. Ewing's sarcoma.
3. Myeloma.
4. Unclassified.
  - (a) Angio-endothelioma.
  - (b) Extraperiosteal sarcoma.

As in many diseases in the past, the knowledge of the pathologic anatomy, diagnosis and, to some extent, the treatment for osteogenic sarcoma has advanced beyond the knowledge of the etiology.

Trauma is thought to play an important part in the production of these tumors, and Coley<sup>3</sup> asserted that 50 per cent of the cases present a history of injury so definitely related to the onset of the tumor that it cannot be ignored as a factor. The history of trauma given by the

patient is frequently not reliable, since it seems to be a part of human nature to try to associate a painful swelling with some injury.

Since osteogenic sarcoma is most prevalent in the young between 10 and 20 years of age who are constantly receiving injuries of various grades of severity, and since the incidence of the disease is quite low, there must be some predisposing factor inherent in the bones so affected. There is much similarity in an active reparative process of growing bone and osteogenic sarcoma. With a loss of growth restraint, this reparative process may eventuate in a malignant tumor. Certainly it seems true that accidental, and even surgical, trauma may cause a malignant change to take place in a benign tumor of the bone.

According to Kolodny, osteogenic sarcoma is understood by the registry committee to mean a sarcomatous tumor derived from the ancestors of cells, which, when duly differentiated, are known as osteoblasts. The adjective osteogenic applied to a sarcoma does not imply that new bone must be produced. In fact, some of the most malignant osteogenic sarcomas form little or no bone. It is true that new bone is usually formed and that at the same time the old bone is being destroyed. Eising<sup>4</sup> described the formation of the perpendicular, fan-like rays of new bone, so characteristic of osteogenic sarcoma, by the stimulating effect produced by the tumor cells on the osteoblasts of the haversian canals. This reactionary formation of new bone follows the vessels outward toward the periosteum. The periosteum also takes an active part in the formation of new bone. Since production of bone signifies differentiation, the tumor containing much bone often pursues a less malignant course than the cellular and vascular growth. Coley thought that the term periosteal sarcoma is a misnomer, since nearly all osteogenic sarcomas start beneath the periosteum proper or have a central origin. He found the classic fanlike radiation shown by the x-ray in only 18 per cent of the cases. Kolodny, in studying the material of the registry, concluded that it was often impossible from the roentgenogram, and even with the gross specimen available, to determine whether the tumor originated from the periosteum or cortex or had a central origin.

There are osteogenic sarcomas the diagnosis of which is quite plain from the clinical and roentgenologic studies. Again, there are tumors which show such variations that the methods of diagnosis, including biopsy and radiotherapy tests, leave one still in doubt as to the true nature of the cases. To err one way may mean the loss of a patient who might have been saved by early radical means. To err the other way may result in an unnecessary, mutilating operation. The average sur-

geon, roentgenologist and pathologist see only a few of these cases, and naturally the doubtful tumors will give great concern as to diagnosis and treatment. Not many of these can avail themselves of the services of the few men who have become expert in this field. It would be helpful for the surgeon to register all of his malignant tumors of the bone and giant cell tumors so that he could study the registry material and at the same time add to the material for the mutual benefit of all interested in the subject. Codman set forth twenty-five criteria which one would do well always to observe in attempting to make a diagnosis of malignant tumors of the bone.

The osteogenic sarcoma which presents the least difficulty of diagnosis will usually be found in a young person, otherwise active and healthy. A good clinical history will usually elicit a complaint of pain, possibly following a trivial injury, and later the appearance of a tumor. The favorite sites for these tumors are the lower end of the femur and the upper end of the tibia. Fifty-two per cent of these tumors are located in the femur. In no instance has an osteogenic sarcoma of the lower end of the tibia or radius been found in the registry material. The clinical appearance of the tumor is somewhat fusiform; the skin is smooth and glazed, and the superficial veins stand out prominently. On palpation the tumor is hard, for the most part, but here and there may be soft or cystic areas. The surface temperature is frequently elevated. The tumor is firmly fixed to the bone and the joint is not involved, but movements of the joint are frequently impaired by the close proximity of the tumor. A roentgenogram will show the newly formed trabeculae of bone and the lipping and elevation of the periosteum up to its firm attachment at the epiphyseal line. The tumor may be seen breaking through the restraining fibrous layer of the periosteum and invading the soft parts. The tumor almost or entirely surrounds the involved bone, but often the shaft will be seen plainly passing through the tumor. In the central and subperiosteal osteogenic sarcomas, the shaft is soon partially or completely destroyed. It is in the latter type of tumor that a pathologic fracture is likely to take place, and since this complication releases the restraint on growth the tumor progresses rapidly and metastases soon follow. One should not be surprised at the absence of the fanlike perpendicular striae of bone because in some of these tumors the bone is laid down parallel to the shaft, and in the large, more slowly growing tumors the x-rays will show a diffuse, irregular spotted appearance of calcification. An osteogenic sarcoma rarely passes through the restraining cartilage; this can be demonstrated on the roentgenogram and after dissection of the gross specimen.

Since the prognosis in osteogenic sarcoma so largely depends on the presence or absence of pulmonary metastases, a roentgenogram of the lungs should always be made. The metastatic tumor may or may not

show formation of bone, depending, according to Eising,<sup>4</sup> on whether or not osteoblasts have been carried to the lungs with the tumor cells.

The first four cases (figs. 1 through 17) of this study were selected because they presented such clear clinical, roentgenologic and microscopic evidence of malignant, typical osteogenic sarcoma of the femur.

During this period of the study, preoperative roentgenologic examination of the lungs was not made as a routine, and it is possible that some or all of these patients had pulmonary metastases before amputation, even though there was no clinical evidence of such lesions. The microscopic sections in each of these four cases showed the characteristic appearance of malignant tumors of the bone, which were diagnosed at that time as osteosarcoma, but which, following the new nomenclature, should be classed with the osteogenic sarcomas. There was no local recurrence or glandular metastasis in any of these patients, but they died within the year following amputation. Three had definite metastases to the lung, and the fourth probably had such metastases.

The fifth and sixth cases (figs. 18, 19, 20 and 21) presented clinical and roentgen evidence as conclusive of osteogenic sarcoma of the femur as that in the first four cases, but biopsies had been done in both cases in other institutions before the patients were admitted to the University Hospital. It has been impossible to secure either slides or tissue from these biopsies, but a diagnosis of malignant disease was reported to the family physician of each patient. In the fifth case, the incision made at biopsy never healed and resulted in a fungating mass. The roentgenogram of the lungs showed metastases. Treatment was refused. In the sixth case, the condition was considered inoperable, and the patient was treated with the mixed toxins of Coley and radiation.

It is in these clearcut, true cases of osteogenic sarcoma, fairly easy of diagnosis, that the prognosis is so poor. The problem of the treatment in these cases is far from being solved. Amputation alone seems to have failed and physicians have turned to radiotherapy, which is still in the experimental stage. Disarticulation or amputation above the proximal joint preceded by radiation locally and to the lungs and followed by radiation and the mixed toxins of Coley seems to me to offer the best chance of arresting the progress of this malignant neoplasm. Cures have been reported following amputation, after radiation and with the mixed toxins and combinations of these. In many of these reported cures there was much doubt as to the malignancy of the tumor. The number of five year cures reported in the literature is too small to create much enthusiasm over any method of treatment.

In sharp contrast to the osteogenic sarcoma is the typical giant cell tumor, which has one-half the incidence of the former neoplasm; it occurs most often in the third decade and is found chiefly in the ends of the long pipe bones, starting in the epiphysis or the extreme end of the

diaphysis but rarely ever involving the joint. The cortex of the bone expands as the tumor grows. Even when the cortex has disappeared the periosteum envelops this tumor, and there is no tendency to invade the soft tissues. If the tumor should break through the periosteum, as sometimes happens after biopsy or pathologic fracture, it does not tend to infiltrate but to grow in the planes of least resistance. The marrow cavity of the shaft is not invaded by the tumor but rather protected by a limiting membrane. As seen on the roentgenogram, the tumor is spherical, trabeculated and multicystic. The shaft of the bone is not present, and there is not the characteristic lipping of the periosteum seen in osteogenic sarcoma. The surface temperature is not usually raised, and superficial veins are rarely dilated. The interior of this tumor has been compared to currant jelly, but in longstanding cases the tumor is more fibrous and solid.

Like osteogenic sarcoma, trauma frequently precedes the appearance of this tumor, but the true etiology has not been discovered.

Codman<sup>5</sup> regarded the giant cell tumor as a benign mass of granulation tissue. Martland<sup>6</sup> thought of it as a phase of osteitis fibrosa cystica. Coley preferred the term giant cell sarcoma, because he found that in certain cases the growth was clinically malignant and death was caused by metastases. He cited six cases in which a diagnosis of giant cell tumor was made, in which the growth proved to be malignant. One of these cases was selected from all the reports of giant cell tumors at the Memorial Hospital and was included by Kolodny in his study of the registry material as showing the most typical example of giant cell tumor. Bloodgood<sup>7</sup> studied 177 cases of giant cell tumor and did not find a single instance of death from metastases.

The histologic structure of the typical giant cell tumor consists chiefly of stroma and giant cells. The stroma is vascular and made up of spindle, round and polygonal cells with vesicular nuclei. The nuclei are not hyperchromatic nor is there much pleomorphism of the cells. The giant cells are opaque, resembling normal osteoclasts with small oval nuclei uniformly shaped and centrally placed.

A good history, physical examination and a roentgenogram will usually lead to a correct diagnosis in the typical case of giant cell tumor. Coley,<sup>3</sup> however, found 20 per cent error in diagnosis based on clinical and roentgenographic evidence alone.

The seventh and eighth cases (figs. 22, 23, 24 and 25) of this report seem to be examples of the typical giant cell tumor. In the seventh case the onset, slow development, pathologic fracture followed by union, roentgenographic appearance and a fourteen year cure after amputation prove the growth to be a benign tumor.

5. Codman, E. A.: *Am. J. Roentgenol.* **13**:105 (Feb.) 1925.

6. Martland, H. S.: *Proc. New York Path. Soc.* **21**:102, 1921.

7. Bloodgood, J. C.: *Surg. Gynec. Obst.* **38**:784 (June) 1924.

The eighth case is more confusing, but the patient's age, clinical history of a pathologic fracture demonstrated by the roentgenogram and subsequent union after fixation and typical roentgen-ray appearance indicate that the tumor is benign. No doubt the appearance of proliferation of bone and infiltration of the soft tissue was caused by the pathologic fracture. The tumor has responded well to roentgen therapy, as indicated by much sclerosing and thickening of the trabeculae, but sufficient time has not elapsed for the patient to be considered cured. A disadvantage of primary radiotherapy in these tumors is that in case of an error in diagnosis valuable time will be lost in instituting radical treatment. Furthermore, radiotherapy should be directed by an experienced, well equipped radiologist since undertreatment has a stimulating effect on neoplastic growth and overtreatment may cause the tissue to break down, or may produce such brittleness that fractures occur easily, or set up an endarteritis, accompanied by such pain that amputation will have to be done.

Unlike the cellular osteogenic sarcoma, the giant cell tumor increases in size and often becomes more painful for a while after radiotherapy.

Many surgeons prefer to treat the giant cell tumor by curettage and swabbing the cavity with an escharotic. There is 20 per cent of recurrence after this procedure, and there is always danger of infection which will be serious and possibly necessitate amputation, particularly if the joint participates in this infection. Repeated curettage for recurrences may transform the benign tumor into a malignant growth. Stone and Ewing<sup>8</sup> reported a case of giant cell tumor in which the condition was completely altered by repeated curettage. There seems to be some doubt, however, as to the primary benign nature of this tumor.

Meyerding<sup>9</sup> studied twenty-four cases of giant cell tumor of the long bones; fifteen of the patients were treated by curettage, five by amputation, three by resection and one by excision. In five of these, subsequent amputation was performed for recurrences and infection, but in no instance was true malignant disease present.

MacGuire and McWhorter<sup>10</sup> studied twenty cases and found that, following treatment, there was no recurrence in twelve cases; seven of the remaining eight developed local recurrences, in two of which the metastasis occurred to the lungs, in one to the inguinal glands and abdomen and in one massively involved the stump remaining after amputation.

10. MacGuire, C. J., and McWhorter, J. E.: Sarcoma of Bone, *Arch. Surg.* 9:545 (Nov.) 1924.

In studying the literature of tumors of the bone, one cannot help but be impressed with the fact that there are various grades of malignancy and many borderline cases in which the diagnosis is difficult. Close cooperation between the surgeon, the roentgenologist and the pathologist is absolutely necessary in the management of these variants. It is in these cases that microscopic examination of tissue removed at biopsy is so essential. When biopsy is done, the surgeon should have permission and should be prepared to do a radical operation in case a malignant condition is found. I see no reason for performing a biopsy on a patient with a hopelessly inoperable osteogenic sarcoma in order to complete the record, since it will certainly increase the rate of growth and will likely cause it to fungate, adding to the misery of the patient till he is relieved by death. If exploration reveals a growth that is suggestive of a giant cell tumor, the whole cavity should be thoroughly curetted and cauterized so that if the pathologist finds the tumor to be benign the proper operative procedure will have been done and the pathologist will have all the tissue for his examination. Too often the pathologist is provided with such meager tissue that it is unfair to expect an intelligent report. The surgeon may or may not follow this curettage with radiotherapy and toxins. Radiation will prevent recurrence but may interfere with sufficient regeneration of bone to give a useful extremity.

Between the true osteogenic sarcomas and the typical giant cell tumors discussed and illustrated in this paper, there are two cases (9 and 10) which seem to me to be borderline or variants. In case 9 the diagnosis at biopsy was osteogenic sarcoma, and amputation was done. This patient was 56 years of age, well beyond the usual age incidence. Seven years before amputation, the clinical and roentgen evidence of a giant cell tumor in the lower end of the tibia was conclusive. The man refused treatment and was not seen until four years later; then, another roentgenogram showed no change in the giant cell tumor, but an erosion on the midportion of the shaft of the tibia was found (case 9 and figs. 26, 27, 28, 29, 30 and 31). Again the patient refused treatment, keeping at his work three years longer and sustaining a pathologic fracture which necessitated his coming to the hospital. The giant cell tumor had increased in size and broken through the capsule. At the site of the tibial erosion a fairly large tumor composed of soft tissue had developed, and a marked contrast was noted between the roentgenogram made three years previously and the one made at this time. The tissue for examination was taken from the tumor on the midshaft. The roentgen-ray films and microscopic slides as well as a clinical record were sent to the chairman and registrar of the Committee on Bone Sarcoma. They have studied this material and concurred in the opinion that this is an atypical case and classified it according to the type of tissue as a mixed cell sarcoma of low grade malignancy. This case is difficult to classify

according to the Bone Sarcoma Registry, there being no classification of mixed cell sarcoma of bone, and the chairman thought that most of the members of the committee would probably classify it as an osteogenic sarcoma.

The tenth case (figs. 32, 33 and 34) is not so confusing as the preceding one, but this patient, too, is beyond the age of highest incidence of osteogenic sarcoma. There was no history of trauma and, as in case 5, pain started in the sole of the foot and in the heel. This pain persisted, creeping up the thigh, for a year before a tumor was discovered. The roentgenogram suggests a giant cell tumor in that there is encapsulation, except where the tumor has broken through in the region of the great trochanter, and definite loculation. New bone, however, extends into the soft tissues and there is destruction of the neck of the femur; the tumor is not sharply defined from the shaft, but destruction of bone seems to be going on at this junction.

The roentgen diagnosis was osteogenic sarcoma, but it seemed wise to do a biopsy in this case. The pathologist made a diagnosis of giant cell tumor but remarked on the possibility of doubt because of the vascular character of the growth, pleomorphism, mitotic figures, true tumor giant cells and tumor ossification.

An amputation at the hip joint was done. The roentgenogram, microscopic slides and a clinical report of this case were also sent to the chairman and registrar of the Committee on Bone Sarcoma; they have classified the tumor as an osteogenic sarcoma, basing their opinion on tumor ossification, although it was of a low type, and on the round and spindle cells showing many mitotic figures and only occasional giant cells.

#### REPORT OF CASES

CASE 1.—M. L., a white girl, aged 16 years, was admitted to the University of Virginia Hospital on Feb. 10, 1911. Three years before admission, she noticed a small hard mass on the lower posterior aspect of the right thigh. Shortly before this mass appeared she sprained her ankle. The tumor was painless, did not interfere with motion of the joint and grew slowly till about a month before she came for consultation. Pain became severe, and movement of the joint was impaired. Loss of weight was noticed.

On the antero-external aspect of the knee was a scar which was caused by the blade of an axe six years previously. The tumor was fixed; the skin was glazed over it, and the surface veins were prominent (fig. 1).

The roentgenogram (fig. 2) shows a marked periosteal proliferation of the lower 9 inches (22.8 cm.) of the femur, reaching a diameter of about 7 inches (17.7 cm.). There was extensive destruction of the cortex. No abnormalities of the chest were found on clinical examination, and unfortunately the importance of routine roentgen examination of the chest was not realized seventeen years ago. A diagnosis of osteogenic sarcoma was made, and amputation was done through the midthigh (fig. 3). Figure 4 shows an island of cartilage and a blood vessel surrounded by tumor cells. Other sections show bone and areas of spindle cells.

Fig. 1 (case 1).—Osteogenic sarcoma of femur.

Fig. 2 (case 1).—Periosteal proliferation and destruction of cortex.

Fig. 3 (case 1).—Gross specimen showing much formation of new bone and destruction of the outline of the shaft.

Fig. 4 (case 1)—Photomicrograph showing islands of cartilage and blood vessels surrounded by tumor cells.

This patient left the hospital at the end of a month, in fair condition. Her family physician, however, reported that she died of pneumonia shortly after returning home. The "pneumonia" was probably pulmonary metastasis.

CASE 2.—J. W., a white boy, aged 12 years, was admitted to the hospital, Jan. 14, 1915. Two months prior to admission, he fell and wrenched his knee. Pain was not severe enough to confine him to the house and disappeared entirely in a short time. One month later, the thigh began to swell just above the knee, and pain became continuous but not severe enough to interfere much with his sleep.

Fig. 5 (case 2).—Fanlike proliferation and lipping of the periosteum and extensive destruction of bone.

The patient was well nourished and apparently healthy except for the tumor of the femur which extended from the midthigh to the knee joint. The overlying skin was glazed, and dilated veins were conspicuous. There was some elevation of surface temperature. Just above the tumor the thigh measured 32 cm., and the maximum circumference around the tumor was 44 cm. The consistency of the tumor on palpation was described as cartilaginous. There were no enlarged lymphatic glands, nor any clinical evidence of metastasis to the lungs

No roentgenogram of the chest was made. The roentgenogram of the femur (fig. 5) shows a fanlike proliferation of the periosteum, lifting of the periosteum and extensive destruction of bone.

A diagnosis of osteogenic sarcoma of the femur was made, and amputation at the hip joint was done. The gross specimen is shown in figure 6. While the shaft of the bone is much damaged, it still can be plainly seen passing through the tumor. This patient made a satisfactory operative recovery but returned to the hospital two months later in an advanced state of emaciation and with a great deal of dyspnea. A roentgenogram of the chest is shown in figure 7.

Fig. 6 (case 2).—Gross specimen showing shaft of bone passing through the tumor.

The patient died in the hospital two weeks after this admission. Autopsy showed the left lung completely replaced by a tumor which pushed the heart to the right and extended well into the right pleural cavity. On section the tumor presented a honeycombed, hemorrhagic, necrotic appearance with one or two areas of bone formation about 5 cm. in diameter.

CASE 3.—C. R., a white girl, aged 15, was admitted to the hospital on Jan. 5, 1915. About five months before admission, she noticed that she became tired easily and that her left knee was painful on exertion. Three months later, she noticed

Fig. 7 (case 2).—Metastases to the lungs.

Fig. 8 (case 3).—Osteogenic sarcoma of the femur.

a hard tumor just above and to the inner side of the left knee. The pain gradually became severe and boring. One month before entering the hospital, she fell and hurt her knee and had not walked since. After this trauma, the tumor grew rapidly (fig. 8).

Fig. 9 (case 3).—Osteogenic sarcoma of the femur with proliferation and destruction of bone and pathologic fracture.

The mass was hard, firmly fixed and not tender. The skin was smooth, and the superficial veins were dilated. The surface temperature was raised, and there was fluid in the knee joint. The leukocyte count was 14,000. A diagnosis of osteogenic sarcoma of the femur was made from clinical evidence and roentgen examination (fig. 9). No roentgenogram was made of the chest.

Fig. 10 (case 3).—Gross specimen showing destruction of bone and fracture line surrounded by tumor.

Fig. 11 (case 3).—Photomicrograph showing spindle cells and several giant cells.

A subtrochanteric amputation was done. The gross specimen is shown in figure 10 and the photomicrographic appearance in figure 11. The stump healed well, and for a while the patient was more comfortable. Signs of metastasis to the lungs developed, and the x-rays showed both lungs infiltrated with tumor (fig. 12). The patient died sixty-five days after admission to the hospital.

CASE 4.—G. H., a white boy, aged 15 years, admitted to the hospital on Feb. 8, 1915, had been a healthy child. One year previous to admission, however, he had pain in his right knee which was diagnosed as rheumatism. Swelling did not appear till six weeks before admission. Two weeks before admission, the patient

Fig. 12 (case 3).—Extensive metastases to the lungs.

fell on the street and sustained a pathologic fracture. The lower portion of the right thigh was considerably enlarged. The skin was glazed, and the superficial vessels were dilated. The surface temperature was elevated. On the inner aspect of the thigh the tumor was soft, but in other places quite firm (fig. 13).

A diagnosis of osteogenic sarcoma was made from the clinical evidence and x-ray plate of the femur (fig. 14). No roentgen examination of the lungs was made, but the clinical examination revealed no signs of metastasis. An amputation at the hip joint was done. The specimen was sawed open; the medullary cavity of the femur contained a yellowish, granular, cellular growth. This had extended through the cortex of the bone and had produced a pathologic fracture.

Fig. 13 (case 4) —Osteogenic sarcoma of the femur.

Fig. 14 (case 4).—Central bone destruction, elevation, and lipping of the torn periosteum. Also a pathologic fracture

The gross specimen is shown in figure 15 and the photomicrographic appearance in figure 16.

This patient died with metastasis to the lungs about one year after operation. The roentgenographic appearance of the chest is shown in figure 17.

CASE 5.—C. G., a negro girl, aged 14, was admitted to the hospital on April 18, 1927. Six months prior to admission, she began to have severe pain in the sole of her left foot. Later, severe pain began in the thigh. One month after this onset, she sought medical advice. A diagnosis of malignant disease was made from material removed on exploration. Amputation was advised, but the family of

Fig. 15 (case 4).—Gross specimen showing destruction of bone, invasion and pathologic fracture.

the patient refused. The tumor grew rapidly, and fungus appeared at the site of biopsy.

On admission to the University Hospital, the patient was in a poor state of nutrition. The left thigh was greatly enlarged and was ulcerating (fig. 18). An x-ray film of the left femur (fig. 19A) showed a massive enlargement, with formation of new bone invading the soft parts. The periosteum was visualized along one-half the extent of the femur.

A flat film of the chest (fig. 20) showed numerous areas, rather circumscribed in appearance and varying in size scattered throughout both lungs.

A diagnosis of osteogenic sarcoma of the femur with metastasis to the lungs was made. The patient's condition was considered hopeless, and the family

would not leave her in the hospital since no cure could be promised. She died several months after leaving the hospital.

CASE 6—B. M., a white woman, aged 22, was admitted to the hospital on May 10, 1924. Nineteen months previous to entering the hospital, she fell from a buggy and bruised her right thigh. Two weeks later, she noticed a swelling on the inner side of the thigh. She was not concerned about this at first, but the tumor grew so fast during the year that she consulted a physician who excised a piece of tissue and gave a diagnosis of malignant tumor of the femur.

Fig. 16 (case 4).—Photomicrograph showing spindle cells and tumor ossification.

This patient presented an undernourished appearance but did not seem to be suffering. She continued to walk, but with considerable disability. The right thigh showed an enormous swelling extending from the knee to the groin. The mass was firm, not tender, and the skin glazed and pigmented; the superficial vessels were greatly dilated. The greatest circumference of the tumor measured 35 inches (88.9 cm.), and the opposite thigh measured 17 inches (42.5 cm.). The right tibia and fibula showed exostoses. The left femur and tibia also showed exostoses. The right ulna showed a marked curved deformity.

Fig. 17 (case 4).—Metastases to the lungs.

Fig. 18 (case 5).—Osteogenic sarcoma of the fémur. Fungus following biopsy.

There was also a curved deformity of the left middle finger and of the left radius and ulna. The right femur is shown in figure 21. According to roentgen examination of the chest, it was doubtful whether pulmonary metastases were present.

This patient had a series of treatments with the mixed toxins of Coley combined with roentgen treatment during May, June and August, 1924. There was little if any improvement. This patient did not return for further treatment. She is dead, but I have been unable to find out the date or any circumstances of her death.

Fig. 19 (case 5).—A massive tumor, with formation of new bone, invading the soft tissues.

It is quite possible that this tumor arose as a result of injury to an exostosis of the femur.

CASE 7.—E. R., a negro, aged 35, admitted to the hospital on Nov. 24, 1914, had pain in the right heel and instep five years before admission. Later, he noticed a tumor on the outer side of the thigh just above the knee. There was little pain, and he did not see a physician for two years, when he fell and fractured the femur. He was seen at the University of Virginia Hospital at this time but refused operative treatment. Union took place, and he got along fairly

well for one year. Pain then became severe, and he had to use a cane and later was driven to the use of crutches.

He insisted on amputation at the time he entered the hospital. The lower end of the thigh was much enlarged. The tumor measured 27 cm. from the upper to the lower limit, and the greatest circumference was 64 cm. The overlying skin was normal, but the superficial veins were dilated. On palpation the mass felt like bone with cystic areas scattered throughout. At the upper limit, the tumor seemed continuous with the shaft of the femur. The patella could be palpated on the anterior and lower aspect of the tumor. Motion of the knee joint was

Fig. 20 (case 5).—Metastases to the lungs.

somewhat impaired and painful. The patient could not bear any weight on the extremity (fig. 22). An x-ray film of the femur (fig. 23) showed a marked cystic, loculated expansion of the cortex to a diameter of  $7\frac{1}{2}$  inches (19 cm.). The cortex was thin, but there was apparently no breaking through.

A diagnosis of giant cell tumor was made from the clinical and roentgen evidence.

A subtrochanteric amputation was done, with good recovery, and the patient was alive fourteen years after operation.

CASE 8.—D. C., a white girl, aged 17 years, was admitted to the hospital on Aug. 18, 1925. She twisted her knee several months previously, and swelling

Fig 21 (case 6).—Osteogenic sarcoma of the femur with marked tumor ossification and invasion.

Fig 22 (case 7) —Giant cell tumor of the femur

resulted and persisted. This was aspirated by the family physician, and bloody fluid was obtained. One month before admission the patient was in an automobile wreck and fractured the upper end of the tibia. The physician advised roentgen examination, and a diagnosis of sarcoma with pathologic fracture was made. When the patient entered the University Hospital, a roentgenogram was made (fig. 24).

Fig. 23 (case 7).—Trabeculation and thin capsule, but no breaking through.

There was marked expansion of the cortex of the upper end of the tibia for a distance of about 4 inches (10 cm). This expanded portion showed areas of rarefaction and apparent trabeculations. At certain points along the expanded cortex there was new bone proliferation running out into the soft tissues. The shaft of the tibia adjacent to the expanded portion showed what was thought to be infiltration or invasion. The shaft below the expansion showed formation

Fig. 24 (case 8).—Giant cell tumor of upper end of the tibia. Pathologic fracture.

Fig. 25 (case 8).—Sclerosis and formation of new bone after radiotherapy.

of new bone along the cortex. This was thought probably to be a giant cell tumor, although the apparent invasion into the soft tissues and into the shaft of the bone below it was against this diagnosis, and was in favor of malignant disease. After consultation, it was decided that this growth was a giant cell tumor.

A roentgen treatment was given, and the fracture was then treated with rest and fixation. Good union was obtained, and further roentgen treatments were given. The follow-up films showed a marked increase in formation of new bone throughout the entire tumor. The trabeculae were much more dense (fig. 25).

Fig. 26 (case 9).—Typical giant cell tumor of the lower end of the tibia.

CASE 9.—F. T., a negro man, aged 56, was seen in December, 1920, complaining of pain just above the left ankle of five months' duration. He attributed this pain to a trivial injury sustained six months previously. X-ray films taken at that time seemed to show a giant cell tumor of the lower end of the tibia. A Wassermann test made at that time gave a doubtful reaction.

One year after the onset of the foregoing condition, the patient noticed a small mass midway between the knee and ankle of the same leg. This mass had slowly increased in size and had caused slight discomfort.

The patient was admitted to the hospital in March, 1924, and a roentgen examination was made. Figures 26 and 27 show the large area of relative rarefaction present at that time in the lower end of the tibia, just above the articular surface.

Fig. 27 (case 9).—An erosion on the shaft of the tibia.

Fig 28 (case 9).—Increase in size of the giant cell tumor which has broken through its capsule and seems to be invading.

This area was fairly well defined, and was apparently not invading the normal bone. There were a few small cross areas of increased density which might be striae of bone dividing this area into loculi. The area was about 2 inches (5 cm.) in length, by about 1½ inches (3.7 cm.) in diameter. Only a shell of cortex was left.

An erosion on the shaft of the tibia was also demonstrated. The patient refused treatment and was not seen again until March, 1927. He continued to have pain in this leg, but it was rarely severe enough to keep him from work. The tumor in the lower end of the tibia had increased somewhat in size, and the tumor in the shaft had increased considerably in size, measuring 16 by 10 cm.

Fig. 29 (case 9).—The site of erosion where a pathologic fracture has taken place and the tumor extending out in the soft parts and invading the marrow cavity.

Several weeks before this last admission, the patient stated that while plowing, his leg gave way under him and that he had been on crutches since. The x-ray films are shown in figures 28 and 29.

The area on the tibia which in 1924 showed a simple erosion now showed an erosion which extended entirely through the shaft. A pathologic fracture with overriding had occurred. There was apparent formation of callus between the upper and lower fragments with irregular vacuolization. There was a large soft tissue tumor over the site of the fracture. The giant cell tumor noted in the

Fig. 30 (case 9).—The tumors are invading, and there is a pathologic fracture with overriding.

Fig. 31 (case 9).—Spindle and polyhedral cells.

lower end of the tibia had increased in size and was apparently breaking through the cortex. The erosive lesion of the shaft of the tibia was thought by the roentgenologist to be a gumma.

Stereoscopic films of the chest showed no pulmonary involvement. A Wassermann test made and repeated at this time was negative. A biopsy was done on the tumor of the shaft, and the report from the quick sections was that of malignant disease. An amputation at the mid thigh was done (fig. 30). The tumor of the shaft was solid, gray and had areas of hemorrhage. The central portion was gelatinous. The tumor had eroded the tibia, leaving 0.5 cm. thick-

Fig. 32 (case 10).—Destruction of the shaft and neck of the femur. The tumor is partially encapsulated but breaking through and invading at one place.

ness and had extended into the narrow cavity for 3.5 cm. The lower end of the tibia presented a smaller tumor, which was firm and loculated, with dimensions of about 6 by 4 cm. It was encapsulated but firmly attached to the bone. There was extension into the marrow cavity as in the larger tumor, and this extension had a similar appearance. The tumor did not extend beyond the epiphysis.

Microscopic sections from the larger tumor (fig. 31) showed areas of loose fibrous tissue with collagen fibrils, areas of myxomatous tissue, more cellular areas, especially around the blood vessels with perithelial appearance, and a few areas of atypical hyaline cartilage. The cellular areas showed hyperchromatic

spheroidal and polyhedral cells. Another section showed solid cellular areas consisting of spindle cells which were hyperchromatic, with a number of foreign body giant cells as well as true tumor giant cells. The small tumor at the lower end of the tibia showed a cellular spindle cell type of tumor. These cells were hyperchromatic. The pathologic report was osteogenic sarcoma.

Nearly two years have elapsed since operation, and the patient is quite well.

CASE 10—Mrs. F. G., a white woman, aged 30, was admitted to the hospital on March 16, 1927. She had been healthy until one year before admission to the hospital, when she began having severe pain in the right heel. This pain

Fig. 33 (case 10).—Gross specimen of tumor showing destruction and invasion of bone.

gradually crept upward, until the knee and then the hip became painful. Three weeks before admission, the patient had severe pain in the region of the right hip and noticed, for the first time, a mass in the region of the great trochanter. Walking became painful. This mass was diffuse, hard, not tender and firmly fixed. It measured about 12 by 10 cm. Twelve centimeters below the anterior superior spines the circumference of the right thigh was 52.5 cm and the left thigh, 50.5 cm.

Figure 32 shows destruction of a portion of the shaft of the femur just below the trochanter, involving only the central portion at this point. The destruction

extended irregularly 3 or 4 inches (7.6 or 10 cm.) below this point. Above the lesser trochanter and extending through the neck up to the head, there was destruction of bone with marked formation of new bone. The cortex was ruptured in the region of the greater trochanter. There was a loculated formation of new bone extending for about  $1\frac{1}{2}$  inches (3.8 cm.) into the soft tissues lateral to the femur.

Stereoscopic films of the chest showed no definite evidence of pulmonary involvement.

Fig. 34 (case 10).—Spindle cells and a few giant cells.

The roentgenologic report, while not conclusive, was osteogenic sarcoma, central in origin. A biopsy was done, but since a benign nature of this tumor could not be clearly established, an amputation at the hip joint was done. The gross specimen and the photomicrographic appearance are shown in figures 33 and 34.

The tumor was encapsulated, involving the greater trochanter and part of the head and neck and about 3 or 4 cm. of the shaft. Part of the tumor was red and gelatinous, but some areas were more light in color and solid. The portion in the shaft was dark red and gelatinous.

Sections from the portion in the shaft showed a vascular and fairly cellular giant cell type of tumor with areas of necrosis. Sections from the white portion near the capsule showed the same picture with large areas of necrosis and hemorrhage. The cells in this area were of the younger type and varied considerably in size and staining property, and there were fewer foreign body giant cells. There were a few spicules of old bone and an occasional true tumor giant cell. This was a cellular giant cell type of tumor, and areas showed cells which varied greatly in size and staining property, and a number of mitotic figures were present. While these tumors are benign generally, the histologic structure of this one was not entirely benign.

This patient was well almost two years after operation and was making remarkably good use of an artificial limb.

#### SUMMARY

My chief purpose in preparing this paper was to record in the literature and in the Registry of Bone Sarcoma some unusual cases of tumor of the bone.

Some osteogenic sarcomas are so typical in their clinical and roentgen manifestations that diagnosis is not difficult. For these patients, however, there is no satisfactory treatment, and the prognosis is poor.

The typical giant cell tumor presents such clear clinical and roentgen evidence that a diagnosis can usually be made without hesitation. The treatment for this lesion is satisfactory, and the prognosis is good.

There are variants, or borderline cases, suggesting in some respects the osteogenic sarcoma and in others the giant cell tumor. Since clinical and roentgen studies have not led to a positive diagnosis, biopsy is resorted to and even then expert pathologists will often disagree as to the benign or malignant nature of the neoplasm.

Radical operation, combined with radiotherapy and the mixed toxins of Coley, should be the treatment of choice in these borderline cases.

# SKIN PRINTS

THEIR USE IN THE DIAGNOSIS OF LESIONS OF THE BREAST \*

JOHN O. BOWER, M.D.

AND

JEFFERSON H. CLARK, M.D.

PHILADELPHIA

The first definite mention of the patterns on the balls of the fingers was made in 1686 by Marcelli Malphigii, Professor of Anatomy of the University of Bologna, who spent an active life in investigating all parts of the human body by means of a recently discovered instrument, the microscope. In 1823, one hundred and thirty-seven years later, Dr. J. E. Purkinge, Professor of Anatomy of the University of Breslau, published a treatise in the form of a small octavo of fifty-eight pages. He described the wonderful arrangements and curving of the minute furrows connected with the organs of touch on the inner surfaces of the hand and foot, especially of the last phalanx of each finger, the curves, the stripes, the loops, the spirals, the whorls, etc. This was the first attempt to classify the patterns of the balls of the fingers. There was no suggestion of the application of these variations in the pattern to the problem of identification. In 1880, two Englishmen living in Asia proposed this idea through the columns of *Nature*. Like all later investigators, they employed prints instead of real fingers in their studies.

Dr. Henry Faulde of Tanskiji Hospital, Tokyo, one of the observers, wrote that these prints could be used for the identification of criminals, but he did not think of the possibility of classifying the impressions or of using them for broader purposes of general identification. He discussed the various directions of study to which the new line of work might lead and anticipated practically everything that has been developed since then, such as heredity, ethnology and comparison with other mammals.

In 1890, Sir Francis Galton proved the individuality and the permanence of finger prints and devised a method of describing and

indexing any number of prints, thus rendering possible the finding of a single print or set of prints in a large collection, and by means of this putting the system on a practical basis.

The identification of persons is based on prints of the friction skin, whether it is finger prints or the larger areas of the palms or the soles and is entirely independent of the sentence or the life of the body to be identified. Disease or death, or even loss of the stratum corneum, does

Fig. 1.—Breast of identical twin corresponding to that of twin shown in figure 2. There is no similarity noted in the size of the areola, the distribution of the pores or the corrugations of the skin.

not interfere with a proper interpretation of the skin print in the area mentioned. In the study of the epidermis covering the breast, such constancy of topography is not present. In addition to ridges, pores and the like, which are present elsewhere, there is the nipple with the orifices of the galactiferous ducts, the areola with the tubercles of Montgomery and the hair follicles.

In 1927, while examining a breast removed from an obese patient, it occurred to one of us that the changes in the skin accompanying the cancer might be depicted with printer's ink, similar to the ordinary thumb or finger print and used for teaching purposes. The pigskin appearance in this particular case was fairly marked; the microscopic observations showed a medullary carcinoma which had been noticed by the patient only six months before. The value of these prints as a diagnostic procedure soon became evident. In conjunction with the

Fig. 2.—Breast of identical twin corresponding to that of twin shown in figure 1. There is no similarity noted in the size of the areola, the distribution of the pores or the corrugations of the skin.

prints, we have been making gross microscopic sections following the technic advocated by Sir G. Lenthal Cheatele of England and Dr. Wainwright of Scranton, Pa. These sections include epidermis or nipple, subcutaneous tissue, breast tissue and growth. By correlating gross and microscopic observations with the prints, we have obtained sufficient data to warrant a preliminary report. Our observations show that the pattern varies with sex and age, in the parous and nonparous

person and in the obese and emaciated person; also in the lactating and congested breast, in acute, subacute and chronic inflammation and in benign growths and cancers.

#### METHOD OF OBTAINING PRINTS

The following is a description of the method used. After the breast is washed with ether or alcohol, the patient is placed in the supine position with the arms on

Fig. 3.—Obstructed duct, note the prominence of the tubercles of Montgomery in the affected breast as compared with the opposite lactating breast shown in figure 4.

a level with the shoulders. One should not touch the nipple with the finger, as this will usually cause it to become more prominent. The breast is anointed with ink, the outfit for taking prints of babies' feet being used. The roller should be applied vertically and horizontally to eliminate the marks made by the edges of the roller. An ordinary pad of moderately heavy white paper is selected for the print. The corners of the paper are then marked, identifying the corresponding

quadrants of the breast. A print of the normal breast should be made first. By so doing, the operator will have some idea of the degree of pressure and the amount of ink necessary. The pad is then applied to the breast from without inward with a moderate degree of pressure. It requires little practice to determine the amount of ink that should be used and the degree of pressure necessary to obtain a good print. It is best to make a series of prints; frequently, the second print is better owing to the removal of excess ink. Naturally, the posi-

Fig. 4.—Opposite breast to that shown in figure 3, the pores are smaller and more sharply defined on the affected side.

tion and the character of the lesion will at times necessitate a varying of the procedure. Sometimes the erect position may help, especially if the breast is small. At other times, the best results are obtained by attaching the paper to a cylinder, similar to a printer's roller, and rolling it over the breast. Printer's ink dries slowly. Blurring may be prevented by the spraying of "Fixatif," a volatile shellac used by artists, lightly over the print. Naturally, manipulation of the involved breast should be avoided as much as possible. Benzine, gasoline or

Fig. 5.—Subacute mastitis. The congestion and swelling of the breast are indicated by marked corrugations around the nipple and the wider spacing of the pores. (The very black areas were caused by adhesive plaster.)

Fig. 6.—Opposite breast to one shown in figure 5.

spirits of turpentine will remove the ink. It is well to follow their use with the application of olive oil to prevent irritation.

#### PURPOSE OF PRINTS

We have used breast prints for the following purposes: (1) identification, (2) teaching, (3) diagnosing physiologic changes and (4) diagnosing pathologic changes.

Fig. 7.—Intracanalicular fibroma. Note the even distribution, the minuteness and the wide spacing of the follicles over the tumor in the upper portion of the breast.

*Identification.*—Our observations seem to indicate that the breast print is as distinctive of the individual as the finger print. Figures 1 and 2 show prints of the breasts of identical twins—even without the aid of a magnifying glass a difference in topography can easily be discovered. Our study of the pores of the breast under high magnification

suggests that they are as individual in characteristics as the pores of the palm. M. Locard reported a case in which positive identification of two suspected criminals was made by means of poroscopy, prints of the palms being available only for study.

*Teaching Purposes.*—Skin prints portray more accurately the integument of the breast than can be demonstrated by any other method. Differentiation between physiologic and pathologic retraction of the

Fig. 8.—Opposite breast to one shown in figure 7.

nipple, obstruction of the ducts, accessory nipples, changes in the tubercles of Montgomery and changes in the pores can easily be noted with the naked eye. In making prints of lesions of the breast, if the growth is sufficiently dense, a definite shading outlines the size of the growth. This is not produced by increasing the pressure at this point while making the print, but is due to an increased density of the tissue beneath.

*Physiologic Changes.*—In prints made from the breasts of juveniles, one can observe the development of the tubercles of Montgomery, and while they make their appearance at varying ages, we have not been able to demonstrate them before the age of 4. At the present time, we are studying prints of breasts made before and during menstruation and before and during the early months of pregnancy. We are not

Fig 9—Fibro-adenoma of the breast of a man The pores are small and are evenly spaced over the lump just beneath the nipple

prepared to make a definite statement regarding the changes incident to the physiologic changes. Changes in the parous and nonparous women, of course, are fairly marked

*Pathologic Changes*—The pathologic changes include. (a) congestive, (b) inflammatory and (c) neoplastic lesions—benign or malignant

There is apparently no change in the size of the pores in congestive lesions. In one case of obstructed duct in a parous woman, the tubercles of Montgomery were definitely accentuated.

In acute inflammatory lesions there is no marked change in the pores. In the print depicted there is a marked change in the size of the areola. The same change was observed in subacute mastitis. In Schimmelbusch's disease no change has been noted in the topography of the nipple

Fig. 10.—Carcinoma simplex. The irregularity and extreme minuteness of pores over the tumor should be noted. Crater-like areas of seborrheic dermatitis can be seen.

or in the size of the pores. In one print taken after operation, the pores were the same.

The topography of the integument covering benign lesions shows no gross change visible to the naked eye. So far we have been unable to note any constant change in the size and shape of the pores and no change in the tubercles of Montgomery or in the areola or nipple itself

in benign lesions. We are enlarging prints and counting and studying the shape of the individual pore. We have not advanced in the study sufficiently to draw any conclusions.

In malignant lesions, it seems possible that the changes in the integument may vary with the type of growth in the breast. We have noted the following changes: The more fibrous the growth the greater the tendency toward obliteration of the pores of the skin. In occasional persons in whom the lesion increased rapidly in size, there seemed to be

Fig. 11.—Opposite breast to one shown in figure 10.

a tendency toward marked increase in the size of the pores. We have noted this in obese women. In breasts in which carcinoma simplex has been diagnosed microscopically, the pores have been smaller. In one case, figure 10, the integument directly over the growth was covered with patches of seborrheic dermatitis. Just what relation these patches bore to the malignant growth is not known. Cross-sections of the entire breast in this case showed cancerous infiltration of the subcutaneous tissue. This was marked enough to produce a visible cupping of the epidermis over the growth. The change in topography of the nipple,

Fig. 12.—Medullary carcinoma in an obese patient (taken after removal of the breast). Extreme retraction of the nipple; large stellate pores due to edema (pigskin), and the disappearance of tubercles of Montgomery and of pores in midportion to the outer side of the nipple are shown.

Fig. 13.—Opposite breast of the same patient in figure 12.

Fig. 14.—Scirrhus carcinoma; flat breast adherent to the wall of the chest. Retraction of the nipple; partial obliteration of the areola and loss of the follicles immediately surrounding it, and tendency to disappearance of the pores beyond the nipple in the upper portion should be noted.

Fig. 15.—Opposite breast of the same patient in figure 14.

of course, depends on the situation of the growth; when the cancerous processes have been close enough to produce a retraction, the halo around the nipple is diminished. If the process involves the areola, there is an obliteration of the follicles.

#### CONCLUSIONS

1. Prints of the human breast depict certain physiologic and pathologic changes more clearly than they can be shown in any other way, making such prints invaluable for teaching purposes.

2. Lesions developing in the tissue of the breast (gland proper) produce changes in the epidermis which we believe are characteristic.

## CONGENITAL DEFORMITIES

*Congenital Dislocation of the Hip.*—Swett<sup>1</sup> described a new method of operative reduction for certain long-standing congenital dislocations of the hip. The steps of the operation consisted of opening the joint capsule, freeing the upper portion of the femur from its attached muscles and of then performing an oblique osteotomy of the femoral shaft just below the trochanters. This procedure freed the upper fragment from the restraining action of the shortened soft parts, and the head could then be placed in the acetabulum quite easily. It was retained in place by overlapping and suturing the redundant portions of the joint capsule. Following the operation, the limb was fixed in plaster or treated in a Thomas splint with extension in order to maintain proper alinement of the femoral fragments. Inevitably there was a certain overriding of the fragments, but union did not fail to develop in any of the patients operated on, and the functional results were reported as satisfactory. The operation was performed on seven hips in four patients.

---

\* This report of progress is based on a review of 160 articles selected from 250 titles dealing with orthopedic surgery appearing in medical literature between June 9, 1928, and Oct. 15, 1928. Only those papers which seem to represent progress have been selected for note and comment.

1. Swett, Paul: J. Bone & Joint Surg. 10:675 (Oct.) 1928.

The author claimed that this method offered a means of reduction in a type of case in which the dislocation had previously been considered irreducible. He considered that the operations thus far performed had been too few and too recent to allow of a final conclusion as to the value of the method but that the only apparent obstacle to its wider use lay in the possibility of too great a degree of disturbed or altered growth and development of the femoral head and acetabulum.

That it was possible to reconstruct the acetabulum in patients with old congenital dislocations of the hip in such a fashion as to deepen the cavity and to give the outer part of the roof a more rounded shape and thus to permit of reduction was demonstrated by Bade.<sup>2</sup> The technic had been worked out on the cadaver, and recently, the operation had been performed successfully on a patient, aged 27. An osteotomy was performed dividing the ilium horizontally from below the anterior superior spine, transversely through the acetabulum. The wing of the ilium carrying the upper half of the acetabulum was then sprung upward and outward from the lower portion by driving an ivory wedge into the gap. This brought the anterior spine into a lateral position in relation to the pubis and descending branch of the ichium.

Gill<sup>3</sup> defined his position in respect to the treatment for old or irreducible congenital dislocations of the hip. He divided the cases into three types: type 1, hips in which there was a shallow acetabulum with the head protruding beyond its upper margin but without complete dislocation; type 2, hips with complete dislocation but in which by open operation the head of the femur could be replaced in the acetabulum without great force or tension; type 3, practically all patients more than 10 years of age in whom there was upward displacement of the head of from 1 to 4 four inches and in whom the head could not be replaced in the original acetabulum at the time of operation or only by the use of excessive force.

In patients with hips of the first type, Gill did not open the capsule but turned down a flap from the ilium and acetabular margin superiorly and posteriorly and filled in the space above with bits of bone removed from the crest of the ilium. In type 2 he opened the capsule, replaced the head in the acetabulum after freeing the cavity of fibrous tissue and then formed a roof, as in type 1. In patients with hips of the third type, in which reduction was out of the question, he formed a new acetabulum by enlarging the old one and then made a roof.

He found that stability of the hip could be assured in all three types. Freedom from pain was almost constant. Mobility was always good in type 1, usually satisfactory in type 2 and quite variable in type 3.

2. Bade, P.: München. med. Wchnschr. **75**:1711, 1928.

3. Gill, A. Bruce: J. Bone & Joint Surg. **10**:696 (Oct.) 1928.

The observations of Allison<sup>4</sup> led him to the conclusion that in congenital dislocation of the hip one was dealing with an embryologic defect and that one should realize that not only was the hip not normal at birth but that throughout the patient's life it would be deformed. This abnormality of growth might so deform the head of the femur as to render normal function of the hip joint impossible. It thus appeared that success or failure following any operative procedure was to some degree dependent on the foreordained changes in the upper femoral region. In other words, reduction of the dislocation did not mean a perfect hip regardless of how the reduction was accomplished. Nevertheless, reduction was necessary and should be attempted at the earliest possible time, both because at this period it was easier to accomplish and because it lessened the secondary changes induced by the faulty mechanics of the unreduced hip. Manipulative reduction in the early years might be successful and should be tried first, but force and resultant injury should be avoided. If the hip could not be reduced easily, open operation offered the better method.

[ED. NOTE.—Out of the welter of controversy that has raged over the subject of congenital dislocation of the hip during the last decade, certain conclusions are beginning to emerge. Growth deformity of the femoral head and acetabulum is the reef on which attempts at manipulative reduction in childhood are frequently wrecked. Concerning the question of how growth deformity may be lessened opinion is divided, and the opponents are ranged in hostile camps over the advantages and disadvantages of the open and the closed method. Allison's idea of an underlying embryonic defect may offer the means of a reconciliation between these opponents. The more fruitful field for investigation is now that of what to do for the old irreducible dislocation. Swett has devised a method which offers hope of diminishing the number of patients included in that category, but which is as yet untested by experience and appears to be surrounded by many pitfalls and dangers. Bade's method is chiefly of academic interest, as yet, but may be capable of development. Gill's conclusions are worthy of study, as they are based on a large experience.]

*Congenital Deformity of the Astragalus.*—Deutschlaender<sup>5</sup> reported on congenital deformity of the astragalus, stating that the condition was not rare since he had encountered it in twelve patients during the course of one year. The appearance of the foot resembled that of severe flat-foot, but differential points were readily discovered on examination. The patients complained of greater pain than was usually experienced in cases of flatfoot. The astragalus stood in nearly a vertical position,

4. Allison, Nathaniel: J. Bone & Joint Surg. **10**:687 (Oct.) 1928.

5. Deutschlaender, K.: Zentralbl. f. Chir. **55**:2848, 1928.

while the os calcis remained horizontal. The scaphoid occasionally showed abnormalities, but it was always found to occupy its normal anatomic position in the skeleton and did not contribute to the deformity of the foot. The bony prominence lying anterior to the internal malleolus was caused by the inward projection and enlargement of the head of the astragalus.

Mau, discussing Deutschlaender's paper, reported that he had obtained good results in this condition after resection of the head and neck of the astragalus.

*Congenital Hallux Valgus.*—Heller<sup>6</sup> encountered the condition of congenital bilateral hallux valgus in a child, aged 7 weeks. Basing his opinion on this case and other clinical experience and, in addition, on a review of the literature, the author stated his belief that hallux valgus might be either congenital or acquired and that a varus deformity of the first metatarsal bone might be one of the several causative factors.

*Congenital Variations of the Cervical Spine.*—Roger, Reboul-Lachaux and Chabert<sup>7</sup> made a study of variations of the cervical spine. They did not include the question of cervical ribs, pointing out that this condition manifested itself in a syndrome that was more brachial than cervical. They classified the other variations under the following headings:

Klippel-Feils' Syndrome and Occipitalization of the Atlas.

I. Klippel-Feils' Syndrome and Occipitalization of the Atlas.

1. From the clinical point of view:

- (a) Shortening of the neck.
- (b) Low implantation of the scalp on the neck.
- (c) Limitation of the motions of the neck, especially in the lateral direction.

2. From the anatomic and roentgenologic standpoint:

- (a) Reduction in the number of cervical vertebrae which were often atrophied and more or less fused together.
- (b) Ascent of the thoracic cage constituting a true cervical thorax.
- (c) The coexistence, among other variations, of a cervical spina bifida.

II. Occipitalization of the atlas was characterized by the following:

1. From the anatomic and roentgenologic standpoint:

- (a) More or less complete fusion between the lateral masses of the atlas and the occiput, either bilaterally or unilaterally.
- (b) Flattening and a hazy appearance of the atlas.
- (c) Rotation of the atlas.
- (d) Frequent association of other cervical anomalies such as cervical ribs and hemivertebral axialization of the third cervical.

6. Heller, Edward: Ann. Surg. 88:798 (Oct.) 1928.

7. Roger, H.; Reboul-Lachaux, J., and Chabert: Paris méd. 1:596 (June 30) 1928.

## 2. From the clinical standpoint:

A congenital torticollis of true bony character, especially marked in case of a unilateral fusion, but well defined even in the bilateral type. This was accompanied by a lateral inclination of the head with rotation, by a limitation of motion, especially in the lateral direction, and often by a difficulty in separating the jaws. Sometimes it was associated with a kyphoscoliosis or facial asymmetry.

The authors pointed out that although the torticollis was of congenital origin it might not manifest itself until the tenth to the twelfth years of age, the period when ossification was becoming complete.

## NUTRITIONAL DISTURBANCES OF BONE

*Irradiated Ergosterol in Rickets.*—After a clinical experience lasting more than a year with irradiated ergosterol, Hess and Lewis<sup>8</sup> stated their feeling that this substance was by far the most potent of the antirachitic agents. It was an absolute specific. Cod liver oil in the amount in which it could be given was a specific of limited dependability—only moderately effective for the average infant, uncertain in action for the rapidly growing infant and ineffective for the premature infant. Treatment with irradiated ergosterol was quite as valuable in tetany as in rickets and in both disorders was remarkable for the rapidity as well as for the reliability of its action. As yet, however, sufficient clinical experience had not been acquired to define its proper dosage. Furthermore, the various preparations could not be evaluated as they had not yet been assayed on the basis of the number of curative units (rats) which they contained. The amounts now recommended and employed were unnecessarily high as shown by the fact that they induced an excess of calcium and inorganic phosphorus in the blood in the normal as well as in the rachitic infant-hypermineralization. Too great emphasis had been laid on rapidity of action. Before beginning distribution of this potent concentrate among members of the medical profession, it seemed advisable to make a more thorough clinical study of its dosage, as had been done in regard to other potent extracts. In view of its reliability, its high degree of activity and its ease of administration, irradiated ergosterol would prove a most valuable addition to the rapidly increasing fund of specific antirachitic agents.

*Experimental Rickets Resulting From Lack of Sunlight.*—Nonidez<sup>9</sup> was able to produce rickets in chicks by giving them an adequate diet but excluding all exposure to direct sunlight. Symptoms of weakness of the leg developed in the third week after this regimen had been inaugurated and went on to typical rachitic changes.

9. Nonidez, J. F.: Am. J. Path. 4:463 (Sept.) 1928.

*Osteomalacia*.—Green-Armytage<sup>10</sup> reported his observations on sixty-nine patients with osteomalacia whom he had followed over a period of three years. He considered that osteomalacia was a food deficiency disease, like rickets. It exhibited multiple clinical types. Tetany and muscle paralyses were common. In some patients, the symptoms were mainly gastro-intestinal. Severe anemia was the rule. Many were so crippled that they could not stand or walk. Sometimes there was complete paralysis from the waist downward. The typical changes in the bones were not always present; they represented a late stage of the disease, and often appeared rapidly. The disease occurred in young girls at puberty and in virgins, but more commonly during lactation and during the third or fourth pregnancy. Improvement of the diet alone had no marked effect, nor did any benefit arise from the administration of calcium alone; but the addition of cod liver oil to the diet or its intravenous administration caused an immediate relief of symptoms, the hobbling, waddling, groaning cripple within a few weeks being able to walk, sit or rise from a chair without pain.

#### GROWTH DISTURBANCES OF THE BONE

*Dyschondroplasia*.—Cleveland<sup>11</sup> reported the case of a boy studied at the New York Orthopedic Dispensary and Hospital who was first seen in 1920, at the age of 2 years. At this time, examination showed that the left leg was 2 inches shorter than the right. Three and a half years later this leg was 6½ inches shorter, and the boy could not walk. In January, 1927, the leg was 7 inches shorter than the right. At this time, tissue was removed from the metaphysis of the tibia for study. It was found to consist of cartilage showing cystic degeneration. Except for the short leg, the patient showed a normal physical development.

The condition was chondrodysplasia of the type known as Ollier's disease and was described as an irregularity in the growth and development of cartilage localized in the epiphyses of the long bones of one side of the body with resulting skeletal deformity. Up to 1924, only fifteen cases besides this one were reported in the literature.

*Larsen-Johansson's Disease of the Patella*.—Larsen-Johansson's disease was described by Hawley and Griswold<sup>12</sup> as a condition in which there was an accessory center of ossification in the patella. It was usually bilateral and frequently associated with Osgood-Schlatter's disease of the tibial tubercle. It occurred in growing children and might give rise to indefinite pain over the patella perhaps associated with some swelling and local tenderness. The authors expressed the belief that the

10. Green-Armytage, V. B.: *Indian M. Gaz.* 63:357 (July) 1928.

11. Cleveland, M.: *Am. J. Surg.* 5:75 (July) 1928.

12. Hawley, George W., and Griswold, Arthur: *Surg. Gynec. Obst.* 47:68 (July) 1928.

disease was essentially traumatic, resulting from a strain of the patellar ligament. Roentgen examination was necessary to establish the diagnosis.

#### TUMORS OF THE BONE

*Osteoblastoma Simulating Osteogenic Sarcoma.*—Rhoads and Blumgart<sup>13</sup> reported the observations in two patients with tumors of the thigh, which microscopically gave the appearance of osteogenic sarcoma. However, the tumors were unconnected with the bone. Both were removed surgically, and there had been no recurrences in the first patient in six months and in the other in two years.

From the study of these cases, the authors concluded that neoplastic bone formation might take place without any connection with primitive or adult bone forming cells. They believed that fibroblasts in any part of the body might give rise to tumor of the bone and that the bad prognosis ordinarily attached to osteogenic sarcoma did not necessarily hold true when the tumor was found unattached to bone.

*Osteitis Fibrosa Cystica of the Spine.*—Adson<sup>14</sup> made a study of two patients with osteitis fibrosa cystica of the spine and drew attention to the fact that this disease might occur in other than the long bones. Both patients were children; one presented symptoms of compression of the spinal cord, but the other complained only of pain and swelling. From his study, the author concluded that the diagnosis might be made with fair certainty from the roentgenograms but ought to be confirmed by exploratory operation, at which time as much of the tumor as possible should be removed and the remaining sac thoroughly curetted.

*Hodgkin's Disease of the Bone.*—The fact that Hodgkin's disease might appear primarily in bone was pointed out by Montgomery.<sup>15</sup> He described a case in which the vertebra, tibia and fibula were first involved and in which, only two and a half years later, the lymph nodes began to be involved. This shows the necessity of complete roentgen examination in all cases of Hodgkin's disease and the importance of examination of the osseous system in all such cases at necropsy.

#### BACK PAIN, SCIATIC PAIN AND OTHER PAIN

*Causes of Low Back Pain.*—O'Ferrall<sup>16</sup> believed that the majority of the acute and many of the chronic backaches occurring in young adults below the age of 45 resulted from sprain of the lumbosacral ligaments. He did not believe that abnormalities of the lumbosacral region alone could account for the symptoms of pain in the back. They were

13. Rhoads, C. P., and Blumgart, H.: *Am. J. Path.* **4**:363 (July) 1928.

14. Adson, A. W.: *Surg. Gynec. Obst.* **46**:684 (May) 1928.

15. Montgomery, A. H.: *Ann. Surg.* **87**:755 (May) 1928.

16. O'Ferrall, John T.: *Low Back Pain*, *J. A. M. A.* **91**:532 (Aug. 25) 1928.

a contributing cause, but the ligamentous and neurologic soft parts were the structures in which lay the real pathologic condition. The lumbosacral joint was normally unstable, and not enough emphasis had been placed on the ligamentous "guy-ropes" and the relation of the bony structures to one another, whereas undeserved importance had been given to the bony abnormalities.

Faulty posture and fatigue were considered by Ewerhardt<sup>17</sup> to be the chief factors in many cases of backache. In such cases pain was usually present low in the back, sometimes radiating down the thigh. Roentgen examination showed no changes or only slight changes, although anatomic abnormalities were often a contributing factor. On examination, lessened mobility of the lower spine with spasticity of the muscles was usually to be found. The fatigue posture with drooped shoulders, prominent abdomen, increased lumbar lordosis, flexed knees and pronated feet was habitual. A poorly developed postural sense was chiefly responsible, and recognition of this fact was fundamental in arriving at a successful solution of the problem.

Discussing a group of patients in which a history was obtained of a relatively sudden onset of pain in the back following a muscular movement of the "surprise type," Heald<sup>18</sup> suggested that the lesion was a minor tear of the inner portion of the quadratus lumborum muscle and of its anterior fascial covering, commencing at the point where it becomes continuous with the ilio-lumbar ligament. In his opinion, the injury was insufficient to cause a dislocation of a joint the size of the sacro-iliac joint. He called attention to the fact that these patients, when lying on their backs, although able to lift each leg separately with the knee extended, were unable to lift both legs together. The patients not cured by lying in bed flat with a pillow under the buttocks, followed by strapping when they were up and about again, were relieved by mobilization under anesthesia; the movement Heald considered most important was hyperextension of the thigh, with the sacrum fixed, the patient lying in the face prone position.

*Referred Pain, "Sciatic" Pain.*—Upson and Nielson<sup>19</sup> reported a series of patients demonstrating the value of roentgenography in the diagnosis of the cause of referred pain. They believed that the radicular cause of pain was far more common than was usually suspected. By tracing the skin areas of individually involved muscles to the corresponding segment of the spinal cord, the neurologist might be able to suggest the segment of the spinal cord in which the pathologic cause of the referred pain would be found. Unless it was possible to establish a definite relation between pathologic changes in the spinal column and

17. Ewerhardt, F. W.: Arch. Physical. Therapy 9:249 (June) 1928.

19. Upson, W. O., and Nielson, J. M.: Am. J. Surg. 4:616 (June) 1928.

the site of pain, the presence of arthritis of the column should not be assumed to be the cause of the pain. Atrophy or fibrillary twitching of muscles was often a good guide to the spinal lesion; pain alone was less reliable, but objective changes in skin sensibility were of extreme importance.

Gierlich<sup>20</sup> stated his opinion that irritation of the root of the fifth lumbar and first sacral nerves might easily be confused with inflammation of the peripheral terminal branches of the sciatic nerve in the calf of the leg and foot unless care was employed in the examination. Severe pain on pressure at a point about 3 cm. lateral to the spinous process of the fifth lumbar vertebra was a characteristic sign of what he termed "root sciatica." In severe cases, there might develop a paresis of the peronei with typical reaction of degeneration. Weakening of the plantar reflex also denoted involvement of the root.

#### SCOLIOSIS

*Rachitic Scoliosis.*—Schede<sup>21</sup> expressed his conviction that the typical rachitic scoliosis resulted from the kyphosis that developed when the rachitic child was allowed to assume the sitting posture too early. The first changes noted were a diminution in the height of the eighth, ninth and tenth dorsal vertebrae, and were secondary to the development of the kyphosis. In order to make the spine erect after these changes had appeared, it was necessary for the child to make a spiral torsion above and below the hump. In many of the patients the changes did not progress, but in others the scoliosis increased with accompanying structural changes.

[Ed. NOTE.—The author has not produced sufficient evidence to prove his point, but his observations may be worthy of additional study.]

*Vital Capacity and Muscle Study in Scoliosis.*—Vital capacity was studied by Flagstad and Kollman<sup>22</sup> in 100 patients with scoliosis, and they reached the conclusion that there existed a definite relationship between it and the location, degree of curve and rotation of the spine. When the height of the curve was in the lower dorsal and lumbar region, vital capacity was not especially affected even in the more severe types of curvature. In mild and moderate forms of curvature, regardless of the muscle power, vital capacity was within normal limits. In severe cases, there was a difference of 13 per cent in vital capacity between the groups of patients with poor muscles and those with good muscles. This suggested that the muscles of the neck, thorax and abdomen had slight influence on vital capacity. In the opinion of the authors, study of the

20. Gierlich, N.: *Med. Klin.* **24**:1621 (Oct. 19) 1928.

21. Schede, F.: *Ztschr. f. orthop. Chir.* **49**:74, 1927.

22. Flagstad, A. E., and Kollman, Sara: *J. Bone & Joint Surg.* **10**:724 (Oct.) 1928.

vital capacity in such cases might give an index as to the damage done and the operative risk in thoracic, spinal and abdominal operations.

*Damage of the Cord in Severe Scoliosis.*—According to Jaroschy,<sup>23</sup> compression of the spinal cord might be encountered not only in patients with congenital scoliosis but also in those with rachitic scoliosis. The symptoms generally manifested themselves during the period of most rapid growth, from the fifteenth to the nineteenth years. The seat of the compression was generally at the level of the fourth dorsal vertebra, usually the narrowest part of the spinal canal. In the patients studied, roentgenologic examination with the aid of iodized oil showed a complete block (in one patient only a temporary block) above the summit of the main curve. In contrast to the observations in tuberculous spondylitis, radicular symptoms were completely lacking. The neurologic picture was that of a complete transverse myelitis in comparison with that of a tumor of the spinal cord in which at first the paralysis would be one sided only. The functions of the bladder and rectum were not affected. The author thought that the lesion consisted, in the early stage, of a swelling of the medulla accompanied by congestion of the blood and lymph. He believed that in the beginning it was justifiable to employ conservative and corrective treatment, but that if relief were not obtained in a short time, laminectomy should be performed. The laminae should be excised on the concave side, and the dura should not be sutured unless this could be done without tension.

*Detorsion and Stabilization of the Fifth Lumbar Vertebra in Scoliosis by Operation.*—Steele<sup>24</sup> devised an operation for scoliosis which he described as "detorsion and stabilization of the fifth lumbar." He was led to the employment of this method by his observations in a patient with scoliosis who showed a marked wedging of the fifth lumbar vertebra. Feeling that a sharp lumbar curve beginning at this point was the cause of the scoliosis, he tried to correct the curve by means of plaster spicas and jackets for as long as four months or until the maximum amount of correction has been obtained. He then employed plaster jackets for about six months. It was found that there was diminution of the curve on inspection but that the only certain improvement that could be demonstrated roentgenographically was a moderate correction of the lumbar curve. This correction was gradually lost when the patient was allowed up and around without a jacket. Steele then resorted to operation to obtain correction. This was done by exposing the lateral articulations of the fifth lumbar vertebra and the sacrum and by removing their cartilage. The fifth lumbar vertebra was then lifted upward and backward by leverage and was fixed in this position by means of a specially shaped wedge of beef bone placed between the articular facets

23. Jaroschy, W.: Beitr. z. klin. Chir. **142**:597, 1928.

24. Steele, P. B.: Am. J. Surg. **4**:493 (May) 1928.

of this vertebra and the sacrum. The writer had performed this operation in six patients, but in only one had sufficient time elapsed for a final estimation of improvement to be made. This patient was followed for two years after operation, and roentgenograms showed that the change of position obtained by the insertion of the wedge between the facets had been maintained with a consequent improvement in the lumbar curve. The ordinary inspection, the symmetry of the trunk as a whole had been and still was steadily improving.

*Scoliosis Treated by Fusion: Three Hundred and Forty-Eight Cases.*—Risser<sup>25</sup> made a preliminary report of the study of end-results of 348 patients with scoliosis in whom operative fusion of the spine had been performed at the New York Orthopedic Hospital. The time period covered was from 1914 to 1926. In approximately one half of the patients, the scoliosis was due to infantile paralysis; in the remainder the etiology was undetermined, with the exception of a few in which it was due to congenital conditions, rickets and empyema.

The author concluded from this analysis that the operation of spinal fusion was one of only moderate severity. More than 50 per cent of the operations were performed in less than one and a half hours. In only a few did the postoperative temperature rise beyond 103 F. The mortality rate was 1.1 per cent. Postoperative shock and pneumonia were the causes of death. An area of natural fusion was found at operation in a few cases. In no instance was this fusion adequate to prevent an increase of deformity. Pseudo-arthritis or failure of fusion occurred in less than 3 per cent of the cases. In these patients, there developed an increase of the curvature at the point of unsuccessful fusion.

Study of the results of the operations showed the necessity of accurate selection of the proper area for fusion. Fusion of the compensatory and not of the primary curve resulted in an increase of the deformity. In a few cases, difficulty was experienced in the determination of what constituted the primary curve. Incomplete roentgenograms were not infrequently responsible for this error. Fusion of the fifth lumbar vertebra and the sacrum was not successful, except in a few cases, in stabilizing a curvature of the lower spine. For a successful result, the stabilized area of the spine must be adequate. In not a few cases, the fusion did not extend low enough. This was especially noticed in the curvatures of paralytic origin and was most marked in those with imbalanced abdominal musculature.

In conclusion, the author stated that "spinal fusion would prevent an increase of scoliosis if the area of fusion was adequate and accurately selected; in older patients, relief from pain would be obtained. This resulted in an improvement in posture and general well being of the patient."

25. Risser, J. C.: Am. J. Surg. 4:496 (May) 1928.

## TUBERCULOSIS

Comparing the results obtained in patients with surgical tuberculosis treated at the Edinburgh City Hospital with and without the addition of heliotherapy, Mekie<sup>26</sup> concluded that the results obtained by the use of artificial heliotherapy when combined with routine treatment in a sanatorium and efficient local treatment did not show any material improvement over the results obtained by treating patients by similar methods but without heliotherapy, and that therefore artificial heliotherapy has not changed the fundamental principles of the treatment for surgical tuberculosis.

Cramer<sup>27</sup> reported the end-results in twenty-three cases of Pott's disease in which Albee's operation had been performed from five to thirteen years previously. In only one case was a good result obtained, and in that case the acute condition healed within six months after the operation. Cramer felt that the operation is indicated only in cases which showed no tendency to spontaneous recovery on conservative treatment, and that the operation should not be done before the twelfth year.

Springer,<sup>28</sup> on the other hand, reported improvement in the patients' general condition following bone grafts to tuberculous spines after the method of Polya.

[ED. NOTE.—The method of Polya, usually called Henle's method in Germany, is said to be older than either the Albee or the Hibbs method. The graft is placed deeply close to the diseased vertebrae instead of being implanted in the spinous processes.]

## ARTHRITIS

Small<sup>29</sup> isolated an organism regularly in cultures from the throats of patients suffering from rheumatic fever or chorea, and named it *Streptococcus cardio-arthritis*. Inoculated into animals, the organism produced lesions of the myocardium, pericardium and valves. Other lesions were produced in the joints, bursae, tendon sheaths and in the central nervous system. Agglutinins were found in the blood of patients suffering from chorea and acute rheumatic fever. An antiserum was obtained and its action observed in 251 cases. Prompt beneficial effects followed its use in acute chorea and in acute rheumatic fever.

Rosenau<sup>30</sup> discussed rheumatic fever from the epidemiologic standpoint. He regarded it as a communicable disease. He showed that

26. Mekie, Eric C.: Brit. M. J. 2:241 (Aug. 11) 1928.

27. Cramer: Surg. Soc. Cologne, Orthop. Clinic, Zentralbl. f. Chir. 55:2198, 1928.

29. Small, J. C.: Ann. Int. Med. 1:1004 (June) 1928.

30. Rosenau, M. J.: Epidemiology of Rheumatic Fever, abstr., J. A. M. A. 90:2136 (June 30) 1928.

frank epidemics do not occur, but that there are house-to-house outbreaks. This may be due to carriers rather than to imperfect sanitation. There has been less rheumatic fever since 1918 than before. Most of the cases occurred in patients between 10 and 20 years of age, with the peak at 12. The colored race is more susceptible than the white. There is a slight predominance of females over males, except during the period of the war. It is a seasonal disease occurring in wet, cold weather. In this country it is more frequent in the spring and in England in the autumn. Like scarlet fever, acute rheumatic fever shows a downward trend as far as mortality occurs. It is related to the streptococcal family of diseases. The epidemiologic kinship confirms the impression that this is the case.

Kinnear<sup>31</sup> estimated that during 1927 rheumatic diseases accounted for one sixth of the total period lost from work by wage earners in Great Britain to whom sickness and disablement benefit insurance was paid. Approximately 5,000,000 pounds were disbursed under the national health insurance scheme during 1927 in Great Britain.

Swift, Derrick and Hitchcock<sup>32</sup> found that the general body reaction in rheumatic fever is allergic in nature probably to streptococci. The type of allergy is that found in tuberculosis and syphilis. It is not serum disease allergy but allergy due to bacterial toxin. It was found that in rabbits which had received an injection of organisms from lesions of joints of patients with rheumatic fever injection of a culture which did not have any effect on the normal rabbit would produce a lesion the size of which varied according to the sensitiveness of the so-called allergic rabbit. The animal sickened and died, showing enlarged lymph nodes and enlarged thymus. At autopsy the bone marrow showed hemorrhages similar to those following the injection of a virulent culture. The culture was really small, but the animal's reactivity had been changed. A focus is necessary to produce a state of allergy. Experiments showed that the allergic state can be removed in rabbits. The authors tried the use of vaccines without giving salicylates and obtained stormy reactions. The patient does not improve until the focus is removed.

[ED. NOTE.—The study of rheumatic fever continues to go hand in hand with the study of arthritis. We publish these abstracts to show the trend of work in that direction. The work of Swift and his associates is probably of great importance.]

Bockoven<sup>33</sup> reviewed 119 cases of infectious arthritis in which the patients were seen in the Veterans' Bureau Clinic. In many of these

cases all foci had been removed, and autogenous vaccines given with no improvement in the arthritis, the disease often progressing in spite of the treatment. According to the author, undiscovered secondary foci may explain this situation.

Gordon <sup>34</sup> reported two cases of chronic articular rheumatism of the spine in which there were symptoms of progressive degeneration of the spinal cord. In both cases, the motor tract only was involved. There was not spasticity, but weakness with increased reflexes; no atrophy was present. The duration in these two cases was from seven to ten years. This condition may easily be overlooked in the early phases of its development. In all cases of oncoming weakness or paresis of the limbs, with or without atrophy, when no cause can be found readily, roentgenograms of the spine should be taken. The author discussed the differential diagnosis between this condition and spastic paraplegia and multiple sclerosis. He expressed the belief that the condition is due to the passage of motor and sensory nerve fibers through an intervertebral foramen which is either narrowed or inflamed by the chronic rheumatism. This condition, he stated, is infrequent.

[ED. NOTE.—While the condition here noted has been previously described, its frequency is probably greater than we are accustomed to believe.]

#### PYOGENIC DISEASES

The experiences of others with the Orr method in osteomyelitis have not been frequently seen in the literature. Brickner <sup>35</sup> did not agree with Orr in several points—not only in the entire avoidance of antiseptics but in the long delay before the first dressing and in the complete immobilization of the part in plaster.

In a series of twenty-four experiments on rabbits, Shands <sup>36</sup> made injections of *Staphylococcus aureus* into the knee joints and studied the effect of sterilizing the joints with gentian violet. A 4 per cent solution of the dye in dextrose was more effective than a solution with sterile water or olive oil, and 85 per cent of the animals were effectively sterilized.

#### POLIOMYELITIS

Flexner <sup>37</sup> reviewed the great epidemiologic events of the past quarter of a century. An account of the pandemics of epidemic cerebrospinal meningitis, poliomyelitis and epidemic or lethargic encephalitis is given. He believed that in earlier times these were all included in a single chain

of causation and probably occurred in connection with the periodic outbreaks of influenza. Modern strides have isolated these various diseases, and in some cases have given methods of prevention and even of cure.

Aycock and Luther<sup>38</sup> reported their experiences with convalescent serum in 106 cases of poliomyelitis in which the patients were seen in the preparalytic stage. By a numerical method of estimation, the average degree of paralysis in the patients receiving treatment was 19 compared to an average of 63.6 in 482 patients not receiving treatment. Furthermore, the amount and severity of the paralysis varied with the interval elapsing between the onset of the disease and the time of treatment, those patients treated on the first day of the disease developing much less paralysis than those treated on subsequent days. The authors concluded, therefore, that there is a favorable effect of convalescent serum when administered in the preparalytic state of poliomyelitis as shown by (1) the low mortality rate, (2) a low average rate for total paralysis, and (3) a strikingly low rate for paralysis of the severer grades.

The intramuscular use of convalescent serum in poliomyelitis was reported by Shaw and Thelander.<sup>39</sup> In a series of eighty-one patients, forty-three of whom received convalescent serum intramuscularly during the active stage of the disease, only thirteen showed paralysis, while of thirty-eight not treated thirty-three showed residual paralysis.

[ED. NOTE.—These reports tend to place the treatment with convalescent serum on a fairly sound basis. The early diagnosis (preparalytic) is absolutely necessary, however, to make this treatment effective.]

Flexner and Stewart<sup>40</sup> pointed out that the use of convalescent serum is based on experimental work done on monkeys. Because of this, they suggested that in the event of severe epidemics passive protection may be afforded to persons menaced by the disease by means of such convalescent serum.

In the last decade three types of serums have been used in poliomyelitis—convalescent serum, Rosenow's antistreptococcus serum and Pettit's serum. Stewart and Haselbauer<sup>41</sup> studied the neutralizing action of both Pettit's and Rosenow's serums on the virus of poliomyelitis. Monkeys were used. The poliomyelitis virus was the Rockefeller Institute strain and was obtained from Dr. Aycock. The Rosenow serum

41. Stewart, F. W., and Haselbauer, P.: *J. Exper. Med.* **48**:431 (Sept. 1) 1928.

was obtained from Eli Lilly & Co. Dr. Pettit furnished his anti-poliomyelitis serum. For controls, convalescent human, convalescent monkey, normal monkey, normal horse and normal sheep serums were used. After the serums and virus had been given ample time for neutralization in vitro, they were used in intracerebral inoculations of monkeys.

The authors concluded that Rosenow's antistreptococcus serum, concentrated or unconcentrated, does not neutralize poliomyelitis virus as tested in monkeys. Pettit's antipoliomyelitis horse serum neutralizes the virus of poliomyelitis only occasionally. Immune sheep serum, prepared according to the method of Pettit, did not neutralize poliomyelitis virus even when the normal serum of the same animals neutralized the virus. The reason for such chance neutralization of virus by normal serum is obscure and must not be confused with the constant virus-neutralizing action of both monkey and human convalescent serums. There is no experimental evidence as a basis for using either Rosenow's or Pettit's serum.

A number of observers have isolated streptococci from tissues of human beings with poliomyelitis and claim for these streptococci partial or complete fulfilment of Koch's postulates. Long, Olitsky and Stewart<sup>42</sup> made a study of streptococci isolated from monkeys affected with experimental poliomyelitis and of three strains of streptococci obtained from Dr. Rosenow. These workers found that a variety of ordinary bacteria, including nonhemolytic streptococci, can be recovered from cultures of the brain of monkeys affected with poliomyelitis. The bacteria were similar to those often recovered from the air of the place in which the cultures were made. The authors could find no etiologic relationship between any of these streptococci and poliomyelitis. Intracerebral injections did not produce poliomyelitis, but purulent meningoencephalitis.

[ED. NOTE.—These experimental observations further strengthen the argument for the use of convalescent serum as opposed to the use of the various streptococcic serums.]

Dickson<sup>43</sup> reported some satisfactory results in stabilizing hips in which the gluteus maximus and gluteus medius are paralyzed. He detached the tensor fasciae femoris from its attachment near the anterior superior spine of the ilium, and transplanted it to a point near the posterior superior spine.

Persons with paralysis of the deltoid were treated by Riedel<sup>44</sup> by transplantation of muscle from three directions. He dislikes arthrodesis

42. Long, P. H.; Olitsky, P. K., and Stewart, F. W.: *J. Exper. Med.* **48**:431 (Sept. 1) 1928.

43. Dickson, Frank: *J. Bone & Joint Surg.* **10**:712 (Oct.) 1928.

44. Riedel, G.: *Ergebn. d. Chir. u. Orthop.* **21**:489, 1928.

because of the winglike scapula produced. For anterior paralysis he uses the pectoralis muscle, for paralysis of the medial portion, the trapezius muscle, and for paralysis of the posterior portion transplantation of both ends of the teres major is recommended.

Jeletzki<sup>45</sup> substituted silk ligaments from the knee flexor muscles for paralysis of the calf group in three cases. The results are said to be satisfactory.

[ED. NOTE.—Silk ligaments are not a satisfactory method of handling deformities and paralyses caused by poliomyelitis. We thought that they were entirely obsolete.]

#### VASCULAR DISEASES

After a comprehensive review of the literature and a large clinical experience, Painter<sup>46</sup> said that as the literature stands today it seems to him that the two significant etiologic factors are, first, a highly sensitized nervous system and vasomotor nerves peculiarly responsive to stimuli from the circulating blood; second, toxic irritants in the form of chemical alkaloids, such as nicotine, which find opportunity, because of retardation of flow and by roughening of the intima, to provide a matrix for the formation of a white thrombus. Because nature puts forth two efforts toward cure, namely, canalization and the development of collateral circulation, Painter advocated prolonged rest and the omission of tobacco as the most reasonable method of treatment.

In a study of the effect on the temperature of ligation of the popliteal vein in thrombo-angiitis obliterans, Morton and Pearse<sup>47</sup> found an increase in surface heat. In all but two cases, there was a coincident clinical improvement in the limb. Their possible explanations are: 1. Manipulation of the vein may result in derangement of the vasomotor mechanism. 2. Possibly occlusion of the deep vein shunts the blood through the superficial vessels, thus causing an increase in temperature of the skin.

#### DISEASES OF THE NERVOUS SYSTEM

McFadden<sup>48</sup> considered most cases of obstetric paralysis due to injury of the suprascapular nerves and expressed the belief that rotation of the head combined with traction downward on the shoulder is the most common factor in causing the injury.

[ED. NOTE.—Such a view can only be condemned as obsolete. The anatomic changes in obstetric paralysis have been so clearly shown by Sever, A. S. Taylor, and others that there seems little need for any attempt at a new explanation of the condition.]
